Hence it appears that the force generated by the oxidation of muscle amounts to only a fifth of that required for the work actually performed, and consequently that the greater part of the muscular force is generated by the non-azotised constituents (fats, carbohydrates) of the animal body (or of the food). A certain quantity of the muscular substance is however oxidised at the same time, and this oxidation gives rise to the nitrogenous constituents of the urine. These views afford an explanation of the fact that during muscular exertion the amount of carbonic acid eliminated is enormously increased, whereas the quantity of nitrogen in the urine exhibits little or no increase (see table, p. 875); also of the necessity for a complicated digestive apparatus in the herbivora, to effect the transformation of the greatest possible quantity of cellulose (Fick & Wislicenus).

Nitrogenous food serves chiefly for the renewal of the muscular substance, although it may also contribute to the development of muscular and nervous power. The muscle may be regarded as a mechanism for converting latent energy into mechanical force, and this force is produced mainly by the oxidation of substances introduced into the blood, not by that of the muscle itself: its production is necessarily accompanied by development of heat, and this is perhaps the only source of animal heat. The muscle, like every other part of the body, is continually renewed, but this renewal does not stand in any direct relation to its function, inasmuch as it is not perceptibly greater during strong exertion than during comparative rest (Frankland).

The connection between the elimination of nitrogen and the development of muscular energy has also been made the subject of an extended series of experiments by Dr. Parkes (*Proc. Roy. Soc.* xv. 339; xvi. 44), the mean results of which are as follows: 1. With a regular addition of nitrogen in the food, the nitrogenous excretion increases slightly during rest as compared with a period of ordinary exercise.—2. The urinary nitrogenous excretion decreases during active exercise as compared with a period of rest, and this decrease is perceptible both when the ingress of nitrogen is stopped, as well as when the nitrogen is supplied in regular amount.—3. After exercise there is an excess, though not great, in the nitrogenous excretion.—4. Nitrogen, when again supplied after having been cut off, is retained in the system after both rest and exercise, and in greatest amount in the latter case, showing that it is needed in the system, and that an insufficient supply must be subsequently compensated.

From these results Parkes concludes that the muscle during its activity takes up nitrogen, and that, parallel with the assimilation of nitrogen, and as a consequence of it, the decomposition of the non-nitrogenous substance surrounding the muscular tissue takes place, which, according to Fick and Wislicenus, is the source of the muscular energy. In the subsequent period of rest, the products of metamorphosis are removed, and the muscle at the same time loses nitrogen. Nitrogen is therefore necessary to the activity of the muscle, and in greater quantity in proportion to the increase of work; and even if severe labour can sometimes be performed on a non-nitrogenous diet, it is possible only for a short time, and at the expense of the nitrogenous constituents of other parts of the body.

Pettenkofer & Voit (*Zeitschr. f. Biologie*, ii. 566; *Chem. Centr.* 1867, p. 779; *Jahresb.* 1867, p. 790) also regard the assumption that muscular power is developed

by the combustion of the non-azotised constituents of food; and that the excretion of urea is merely a consequence of a constant consumption of the muscles, as incorrect, especially because this consumption does not increase during exercise. They regard it as more probable that the storing up of albumin in the body, and the condensation of oxygen thereby, forms a reservoir for the muscular power, which can be drawn upon at pleasure (perhaps by elimination of oxygen and formation of carbonic acid and water from fat). The accumulation of disposable or potential energy takes place therefore but slowly, and by no means in proportion to the quantity of the products of combustion which are formed in the course of 24 hours. Before the elimination of carbonic acid can be increased in proportion to a more abundant supply of food, a larger quantity of oxygen must also be taken up, and this increased faculty of absorbing oxygen is but slowly acquired by the organism. Hence persons who have been badly nourished may live on a generous diet for a considerable time before they recover their full normal muscular power; and to patients suffering from diabetes or leukaemia (in whom the power of absorbing oxygen is defective), strong muscular exertion is impossible, in spite of the most abundant nutriment. See further the experiments of Pettenkofer a. Voit (*Ann. Ch. Pharm.* cxli. 295; *Sitzungsber. d. Bayerischen Akad. d. Wissensch.* 1867, 1; *Zeitschr. f. Chem.* [2] iii. 30; *Phil. Mag.* [4] xxxiv. 30; *Jahresb.* 1866, p. 723; 1867, p. 781).

O

OBREGUIN. A substance intermediate in character between the fats and resins, occurring in Mexico on the twigs of *Alcea rosea*. It is nearly insoluble in alcohol, easily soluble in ether, chloroform, and turpentine oil, and remains, on evaporating its solutions, as a colourless inodorous mass, having the consistence of turpentine, and saponifiable by alkalis.

OCTANE. C^8H^{18} .—This hydrocarbon is one of the constituents of American petroleum. It is produced by the action of zinc and hydrochloric acid on secondary octyl iodide (Schorlemmer, *Proc. Roy. Soc.* xvi. 329); by that of sodium-amalgam on primary octyl iodide (Zincke, p. 878); and, together with others of the same series, by heating phthalic acid, $C^8H^8O_4$, indigo blue, $C^{12}H^8NO$, and acenaphthene, $C^{12}H^{10}$, with 80 pts. of saturated aqueous hydriodic acid (Berthelot, pp. 3, 728, 741); by the dry distillation of the lime-soap of Menhaden oil; and, according to Vohl (*Jahresb.* 1865, p. 841), by passing the vapour of tridecane, $C^{13}H^{28}$, through a red-hot iron tube.

The isomeric modifications of octane have not yet been very completely investigated. Schorlemmer (*Proc. Roy. Soc.* xvi. 370), from a comparison of the boiling point (124°) of octane obtained from secondary octyl alcohol with those of quintano (amyl hydride), C^8H^{12} , hexane (ethyl-butyl), C^6H^{14} , and heptane (ethyl-amyl), C^7H^{16} , infers that it has one of its carbon-atoms associated directly with three others—in other words, that it contains the radicle isopropyl—and is represented by the formula

(see HYDROCARBONS, p. 709). From the experiments of Zincke (*Ann. Ch. Pharm.* clii. 16), it appears that octane prepared from primary octyl iodide has very nearly the same boiling point and specific gravity as that obtained from the secondary octyl iodide; and recent experiments by Schorlemmer (*ibid.* clii. 153) have shown that the octane from secondary octyl iodide and that obtained from petroleum yield, by conversion into octyl chloride and acetate, and saponification of the latter, both a primary and a secondary octyl alcohol: hence it seems probable that these hydrocarbons are themselves mixtures of two isomeric compounds; in fact, the octane from petroleum may be separated by long-continued fractional distillation into two hydrocarbons, C^8H^{18} , one boiling at 119° – 122° , the other at 122° – 125° .

OCTYL or DIOCTYL. C^8H^{18} , is produced, together with octane, when primary octyl iodide is heated with sodium-amalgam, and the product is subsequently rectified over sodium; it is easily separated from the octane by its higher boiling point, and may be purified by dissolving it in a small quantity of ether-alcohol, and cooling the solution by a freezing mixture, whereupon it solidifies to a crystalline pulp, which, after the liquid has been quickly filtered off in the cold, must be washed with

well-cooled alcohol and repeatedly pressed. It then forms white laminae having a strong sacreous lustre, soluble in hot absolute alcohol or in ether, and separating from either solution in well-defined crystals. Hot concentrated alcoholic solutions become turbid on cooling, yielding drops of oil which afterwards solidify. Octyl melts at 21° and boils constantly at 278° (Zincke).

OCTYL ALCOHOLS AND ETHERS. *Primary Octyl Alcohol*, or *Hep-tylcarbinol*, $C^8H^{17}.CH^2OH$, and the corresponding *acetate*, $C^8H^{15}.CH^2OC^2H^3O$, are contained in the volatile oil obtained from the seeds of the cow-parsnep (*Heracleum Spondylium*). The comparatively small portion of this oil which boils between 190° and 195° consists mainly of the alcohol; but by far the greater portion passes over between 200° and 212°, and this by continued fractionation, yields primary octyl acetate, $C^{10}H^{20}O^2$, boiling between 206° and 208°. This compound is insoluble in water, easily soluble in alcohol and ether, and has a sp. gr. of 0.8717 at 16°. Heated with alcoholic potash, it yields potassium acetate, and an oil which floats on the surface and distils completely between 185° and 195°. To obtain the whole of it, the alkaline liquid is mixed with common salt, and the separated oil is washed therewith, then dried with fresh quick lime, and distilled.

The colourless oily liquid thus obtained is primary octyl alcohol. It has a sp. gr. of 0.830 at 16°, boils between 190° and 192°, is nearly insoluble in water, miscible with alcohol and ethers, has a peculiar pungent aromatic odour, and tastes sweetish at first, afterwards burning and sharp (Zincke, *Ann. Ch. Pharm.* clii. 1).

By boiling for some hours with potassium dichromate and dilute sulphuric acid, this alcohol is converted into an acid, $C^8H^{14}O^2$, melting at 16° to 17°, and isomeric or identical with the caprylic acid of natural fats, together with the corresponding octylic ether, $C^8H^{17}.C^8H^{15}O^2$. This reaction shows it to be a primary alcohol; and from the boiling point of the octane derived from it (p. 897), it appears to be an iso-alcohol, that is to say, to contain the radicle isopropyl. The structural formulæ of the alcohol, and of the caprylic acid derived from it, are accordingly:

If the alcohol were a normal alcohol, the octane derived from it should boil, if Schorlemmer's views are correct, at 131.5°. (See *HYDROCARBONS*, p. 709.) The boiling points of the alcohol and its derivative are (like those of primary alcohols and ethers in general) considerably higher than those of the corresponding secondary octylic compounds derived from castor-oil alcohol (Zincke, *Ann. Ch. Pharm.* clii. 1).

Primary octyl alcohols are likewise obtained from octane by converting that hydrocarbon into octyl chloride, then into acetate, and saponifying the latter with alcoholic potash; secondary alcohols are however formed at the same time. The primary alcohol thus obtained from octane prepared from secondary octyl iodide, yields by oxidation with chromic acid mixture, an acid having the composition $C^8H^{14}O^2$, but differing both from the caprylic acid of natural fats, and from that obtained by oxidation of the octylic alcohol of *Heracleum* oil, inasmuch as when floating on water it remains liquid when cooled to 0°: hence the primary octyl alcohol from this variety of octane appears to be different from that of *Heracleum* oil. Octane from petroleum likewise yields a primary alcohol convertible by oxidation into an acid, $C^8H^{14}O^2$; but the quantity obtained was too small for the determination of its physical properties (Schorlemmer, *ibid.* clii. 152).

Primary Octyl Chloride, $C^8H^{17}Cl = C^8H^{15}.CH^2Cl$, is best prepared by saturating the alcohol from *Heracleum* oil at a low temperature with hydrochloric acid gas, heating for some time to 120°, and converting the small portion of the alcohol which then remains undecomposed, with phosphorus chloride. The *bromide* and *iodide* are obtained by treating the alcohol with bromine or iodine and red phosphorus. These three ethers are colourless liquids, insoluble in water, sparingly soluble in weak spirit, easily soluble in absolute alcohol and ether. Their boiling points and specific gravities are as follows:

	Boiling point	Sp. gr.
Chloride, $C^8H^{17}Cl$. . .	179.5°–180.5° . . .	0.8802 at 16°
Bromide, $C^8H^{17}Br$. . .	198°–200° . . .	1.1116 „
Iodide, $C^8H^{17}I$. . .	220°–222° . . .	1.1338 „

The primary octyl ethers of the fatty acids are colourless oily liquids, insoluble in water, soluble in alcohol and ether, and exhibiting an average difference of 16° in boiling point for each difference of CH^2 :

		Boiling point	Sp. gr.
Acetate,	$C^8H^{17}.C^2H^3O^2$	206° to 208°	0.8717 at 16°
Valerate,	$C^8H^{17}.C^4H^7O^2$	249° " 251°	0.8642 "
Caproate,	$C^8H^{17}.C^6H^{11}O^2$	268° " 271°	—
Caprylate,	$C^8H^{17}.C^8H^{15}O^2$	297° " 299°	0.8625 "

The acetate and caproate exist ready-formed in Heracleum oil; the caprylate was obtained by oxidising the alcohol with chromic acid; the valerate by heating the bromide in sealed tubes with potassium valerate (Zincke).

Secondary Octyl Alcohols.—The eight-carbon alcohol obtained from castor-oil (iv. 170) is converted by oxidation with chromic acid mixture into a ketone, namely

methyl- α -nanthol or methyl-hexyl ketone, $C \begin{Bmatrix} CH^3 \\ C^6H^{13} \\ O \end{Bmatrix}$, which, by further oxidation,

yields acetic and caproic acids: hence this alcohol consists of methyl-hexyl

carbinol, $C \begin{Bmatrix} CH^3 \\ C^6H^{13} \\ H \\ OH \end{Bmatrix}$. Further, by converting it into the corresponding iodide, and

treating this iodide with zinc and hydrochloric acid in a flask surrounded with cold water, octane, C^8H^{18} , is obtained as an oily liquid, which when freed from adhering traces of iodide and alcohol by treatment with nitric and sulphuric acids, boils at 124°. This hydrocarbon is inferred, from considerations already adduced, to contain the radicle isopropyl (p. 709), and accordingly the alcohol from which it is produced

is regarded as constituted according to the formula $C \begin{Bmatrix} CH^3 \\ CH^3CH^2CH^2CH(CH^3) \\ H \\ OH \end{Bmatrix}$

(Schorlemmer, *Proc. Roy. Soc.* xvi. 376).

The same alcohol is obtained, together with a very small quantity of the primary alcohol, from the octane of American petroleum. This liquid treated with chlorine yields an octyl chloride, $C^8H^{17}Cl$, having an odour of oranges, and boiling at 173° to 176°; the latter heated to 200° with strong acetic acid and potassium acetate, is converted into octylene, together with a comparatively small quantity of octyl acetate, a liquid having an odour of pears and boiling at 200°–205°; and by heating this acetate with alcoholic potash-solution, treating the resulting liquid with water, washing the oily liquid thereby separated several times with water, and drying it over fused potash, an octyl alcohol is obtained boiling at 180°–182°, having exactly the same odour as the castor-oil alcohol, and yielding by oxidation (together with a little caprylic acid) the same products of oxidation as the latter.

Another secondary octyl alcohol is obtained, together with a larger proportion of the primary alcohol, by a similar series of operations on the octane produced by reduction of the secondary octyl iodide corresponding to castor-oil alcohol (p. 877). This octane yields a chloride having but a slight odour of oranges, boiling at 174°–176°, and likewise converted by heating with alcoholic potash into octylene and octyl acetate; but these two products are formed in about equal quantities, whereas the octyl chloride from petroleum octane yields about three times as much octylene as octyl acetate. The acetate thus obtained has also an odour of pears, and boils at 198°–202°. The alcohol prepared from it by heating with alcoholic potash boils between 180° and 190°, the greater portion between 182° and 186°. It smells very much like methyl-hexyl carbinol, and likewise yields, by oxidation with chromic acid mixture, an acid, $C^8H^{16}O^2$, isomeric with caprylic acid, and a ketone isomeric with methyl- α -nanthol; but this ketone yields by further oxidation, propionic and valeric acids, without a trace of acetic: hence it consists of ethyl-caproyl or ethyl-

amyl ketone, $C \begin{Bmatrix} C^2H^5 \\ C^6H^{11} \\ O \end{Bmatrix}$, and the alcohol which yields it is ethyl-amyl carbinol,

$C \begin{Bmatrix} C^2H^5 \\ C^6H^{11} \\ H \\ OH \end{Bmatrix}$ (Schorlemmer, *Ann. Ch. Pharm.* clii. 152).

A secondary octyl alcohol, perhaps different from both the preceding, is obtained from octylene (De Clermont, *Compt. rend.* lxvi. 1211; *Ann. Ch. Pharm.* cxlix. 38). This hydrocarbon heated in a sealed tube with saturated aqueous hydriodic acid is converted into secondary octyl iodide, or octylene hydriodide, $C^8H^{16}.HI$; the latter is decomposed at ordinary temperatures by silver acetate, yielding a secondary octyl acetate or octylene monoacetate, $C^8H^{16}.HC^2H^3O^2$, together with octylene and acetic

acid; and the acetate distilled with finely pulverised potassium hydrate, yields the secondary octyl alcohol, which for distinction may be provisionally called octylene hydrate.

This alcohol, $C^8H^{18}O$ or $C^8H^{16}.H^2O$, is, after rectification, a colourless, mobile liquid, which does not stain paper, has an aromatic odour, and a burning persistent taste, is insoluble in water, but soluble in alcohol and ether; burns with a luminous flame. Boils at 174° – 178° (lower than either of the preceding modifications); has a sp. gr. of 0.811 at 0° and 0.793 at 23° . It is not decomposed by heating to 280° for twenty hours. By oxidation with chromic acid mixture at the boiling heat it is converted, partly into methyl-cenanthol, partly by further oxidation into acetic and caproic acids. It yields, therefore, the same oxidation-products as octyl alcohol from castor-oil, and must therefore consist, like the latter, of methyl-hexyl carbinol; but its boiling point, and those of the corresponding ethers, so far as they have been examined, are lower than those of the castor-oil alcohol and its compound ethers: it is probable therefore that the hexyl radicles in the two alcohols are differently constituted (De Clermont, *Bull. Soc. Chim.*, [2] xii. 212).

Octylene hydriodide, obtained by heating octylene or the alcohol with saturated hydriodic acid, has a sp. gr. of 1.314 at 21° , and boils at 120° (the iodide from castor-oil alcohol at 193° according to Squire, 210° according to Bouis). The *hydrobromide* boils at a lower temperature. The *acetate* has a sp. gr. of 0.822 at 0° and 0.803 at 26° , and boils at about 176° (that from the castor-oil alcohol at 193° Bouis).

Tertiary Octyl Alcohol or *Propyl-diethyl Carbinol*, $C \begin{Bmatrix} C^3H^7 \\ C^2H^5 \\ C^2H^5 \\ OH \end{Bmatrix}$, is

produced by treating butyryl chloride, C^4H^7COCl , with zinc-ethyl, leaving the product for several days till it becomes viscid, then heating it in the water-bath, acidulating with hydrochloric acid, and distilling. The tertiary alcohol then passes over, and after being freed from an admixed ketone by agitation with sodium bisulphite, may be purified by distillation over ignited potassium carbonate. Its formation is represented by the equations:

This alcohol is similar in its properties to the tertiary butyl and hexyl alcohols (pp. 374, 698), being a somewhat viscid liquid, lighter than water, and slightly soluble therein; it has an alcoholic and camphorous odour and does not solidify in a freezing mixture. With phosphorus pentachloride it forms an octyl chloride, $C^8H^{17}Cl$, having a peculiar and unpleasant odour, and boiling at 155° . By oxidation with chromic acid mixture it yields propionic and acetic acids (Buttlerow, *Bull. Soc. Chim.* [2] v. 17).

OCTYLENE ACETOCHLORHYDRIN. $C^8H^{16}.ClO^2 = C^8H^{16} \begin{Bmatrix} OC^2H^3O \\ Cl \end{Bmatrix}$.

This compound is produced by direct combination of octylene with aceto-hypochlorous anhydride or chlorine acetate, $ClC^2H^3O^2$, prepared by Schützenberger's method (p. 25). Hypochlorous anhydride prepared from dry chlorine and mercuric oxide is passed into 50 grams of acetic anhydride cooled to a low temperature, till an increase of weight amounting to 10 grams has been attained, whereby the liquid is one-fourth saturated; this limit must not be exceeded, for fear of explosion. The mixture is added by drops to 14 grams of pure octylene, previously diluted with acetic anhydride and glacial acetic acid, and cooled by a freezing mixture to moderate the action. Combination then takes place, attended with rise of temperature, and on subsequently adding water, the acetochlorhydrin separates, and may be purified by washing with water, drying over calcium chloride, and rectification. It is a light mobile liquid, having a pleasant aromatic odour and burning taste; soluble in alcohol, ether, and acetic acid, insoluble in water; burns with a bright green-edged flame. Boiling point 225° . Sp. gr. = 1.026 at 0° , 1.011 at 18° . Vapour-density obs. = 7.32; calc. = 7.12. It is not altered by cohobation for several days with

caustic potash, but when heated to 180° in a sealed tube with potassium hydrate for forty hours, it is partially saponified, the product yielding by fractional distillation a liquid which boils at 145° , and has nearly the composition of octylene oxide, $C^8H^{10}O$ (De Clermont, *Compt. rend.* lxxviii. 1323; *Zeitschr. f. Chem.* [2] v. 469).

CENANTHOL-UREAS. See UREA.

OILS and FATS. For the extraction of oils from seeds, H. Vohl (*Dingl. pol. J.* clxxxii. 319; *Jahresb.* 1866, p. 893) recommends the light hydrocarbons of Canadian petroleum boiling at about 60° (which he calls *Canadol*), instead of carbon bisulphide.

On the testing of fixed oils, see Donny, *Bull. Soc. d'Enc.* 1864, p. 372; *Dingl. pol. J.* clxxiv. 78; *Jahresb.* 1864, p. 734;—Dragendorff, *Russ. Zeitschr. Pharm.* ii. 434; *Jahresb.* 1864, p. 734;—Nicklès, *Bull. Soc. Chim.* [2] vi. 89; *Jahresb.* 1866, p. 827;—Jacobsen, *Bull. Soc. Chim.* [2] vii. 96; *Jahresb.* 1866, p. 827.

A method of determining the quantity of fatty oil in seeds, &c., by exhausting the substance with a volatile solvent, as ether, benzene, or carbon bisulphide, evaporating the solvent, and weighing the residual oil, is described by R. Hoffmann (*Zeitschr. anal. Chem.* vii. 368; *Zeitschr. f. Chem.* [2] iv. 530).

The amount of oil obtainable from various seeds, European and exotic, has been determined by Cloez (*Bull. Soc. Chim.* [2] iii. 41–50; *Jahresb.* 1865, p. 629), and by Münch (*N. Jahrb. Pharm.* xxv. 8; *Jahresb.* 1866, p. 698); from seeds of various Indian plants by J. Lepine (*J. Pharm.* [2] xl. 16; *Jahresb.* 1861, p. 741). The proportion of olein, stearin, and palmitin in the seeds of various Indian plants has been determined by Oudemans (*J. pr. Chem.* xcix. 407; c. 409; *Bull. Soc. Chim.* [2] viii. 121; *Jahresb.* 1866, p. 696).

Mège-Mouries (*Compt. rend.* lviii. 864; lx. 735; *Jahresb.* 1864, p. 809) describes a new method of saponification, founded on the property of fats in the state of emulsion (*état globulaire*) to take up soda-ley containing common salt. See also De Milly and Lagraud, *Bull. Soc. d'Encouragement*, 1864, xi. 406, 410; *Dingl. pol. J.* clxxvi. 145, 151; *Jahresb.* 1865, p. 843;—F. Knapp, *Dingl. pol. J.* clxxx. 309; *Jahresb.* 1865, p. 844.

A detailed account of the methods in use for the manufacture of fatty acids, with an experimental examination of the various statements relating to the decomposition of fats by sulphuric acid, is given by J. Stas ('Auszug aus einem Bericht über die Londoner Industrie-Ausstellung von 1862,' aus *Schweizerische polytechn. Zeitschrift*, ix. 138, in *Dingl. pol. J.* clxxv. 68; *Jahresb.* 1865, p. 845).

On the saponification of fats by lime, see H. L. Buff (*Inauguraldissertation Göttingen*, 1863; abstr. *Dingl. pol. J.* clxxiii. 53; *Jahresb.* 1864, p. 808). The same author (*loc. cit.*) has given a report on the manufacture of fatty acids and glycerin, and a history of the investigations relating to the chemical nature of fats.

OKENITE. According to E. E. Schmid (*Pogg. Ann.* cxxvi. 148; *Jahresb.* 1865, p. 889), this mineral gives off two-thirds of its water at 100° , being thereby reduced to $3(CaO.2SiO_2) + 4H^2O$.

OLEIC ACID. $C^{18}H^{32}O_2$ (Overbeck, *J. pr. Chem.* xxvii. 159; *Zeitschr. f. Chem.* [2] i. 509; ii. 186; *Jahresb.* 1865, p. 326; 1866, p. 330).—When 1 mol. bromine is gradually added to cooled oleic acid, oleic dibromide (or dibromostearic acid), $C^{18}H^{32}Br_2O_2$, is produced, and may be purified by saponifying it with dilute potash-ley (containing not more than 1 mol. KHO to 1 mol. of the dibromide), dissolving the white soap-cake in dilute alcohol, decomposing it with hydrochloric acid, dissolving the washed oil in ether, and evaporating, finally over sulphuric acid. It then remains as a yellow syrupy oil, heavier than water, insoluble therein, easily soluble in alcohol and ether, and not decomposing till heated above 100° . Its salts are viscid, unctuous, or gummy masses. When crude oleic acid which had been altered by exposure to the air was treated with bromine, a buttery product was obtained, the solution of which in a small quantity of alcohol deposited granular crystals having nearly the composition $C^{18}H^{32}Br_2O_2$ (iv. 194).

Monobromo-oleic acid, $C^{18}H^{31}BrO_2$, is produced by mixing the dibromide with at least 2 mol. potassium hydrate in alcoholic solution. The solution decanted from potassium bromide, and considerably diluted with water, deposits a light yellow oil, which when left to itself in a vacuum, yields white crystals melting at 35° to 36° , and probably consisting of monobromo-oleic acid containing a small quantity of stearic acid. It is reduced to oleic acid by sodium-amalgam. *Monobromo-oleic dibromide* or *tribromostearic acid*, $C^{18}H^{31}Br_3O_2$, is formed by direct union of bromoleic acid with bromine, as a limpid viscid oil, easily soluble in alcohol and ether. Alcoholic potash removes part

of the bromine at ordinary temperatures, and the whole when heated, forming stearolic acid.

Elaïdic dibromide (Burg's dibromelaïdic acid) is likewise converted into stearolic acid by heating with alcoholic potash to 180°.

OLEOPHOSPHORIC ACID. See LECITHINE (p. 779).

OLIVIN. On the occurrence of this mineral in trap-rocks and other formations, see Tschermak (*Wien. Akad. Ber.* lii. [1] 265; lvi. [1] 261; *Jahresb.* 1865, p. 923; 1867, p. 1025). On olivin in meteorites: Daubrée (*Compt. rend.* lxii. 200, 369, 666; *Jahresb.* 1866, p. 1002). On olivin-rock: Sandberger (*Jahrb. Min.* 1866, p. 385; *Jahresb.* 1866, p. 978) and Kjerulf (*Jahrb. Min.* 1867, p. 480; *Jahresb.* 1867, p. 1025).

OPIANIC ACID, $C^{10}H^{10}O^5$, is formed, together with other products, by boiling an alcoholic solution of narcotine-tri-iodide (*Jørgensen*, p. 865).

Opianic acid heated with concentrated hydrochloric or hydriodic acid, is converted, with evolution of methyl chloride or iodide, into methyl-noropianic acid, $C^9H^9O^5$, a compound intermediate between normal opianic acid (see NARCOTINE) and opianic (dimethyl-noropianic) acid:

$C^9H^9O^5$
Normal
opianic
acid.

$C^9H^9O^5$
Methyl-
noropianic
acid.

$C^{10}H^{10}O^5$
Opianic
(dimethyl-noropianic)
acid.

Methyl-noropianic acid is monobasic. It dissolves in cold, but more easily in boiling water, and crystallises therefrom with $2\frac{1}{2}$ mol. water. Like hypogallic acid, it forms with ferric chloride a dark blue liquid, which, however, on addition of ammonia, becomes, not blood-red, but light red. By dilute nitric acid it is converted into *nitromethyl-noropianic acid*, $C^9H^7(NO^2)O^5$, which crystallises with 1 mol. water (Matthiessen a. Foster, *Chem. Soc. J.* [2] vi. 357).

OPINIC and ISOPINIC ACIDS. $C^{14}H^{10}O^8$.—Isomeric acids produced, according to Liechti (*Zeitschr. f. Chem.* [2] vi. 196), by the action of hydriodic acid upon hemipinic acid:

The oxalic acid is resolved by the further action of the hydriodic acid into water and the oxides of carbon. The two isomeric acids crystallise from the solution, and are easily separated by recrystallisation. *Opinic acid* crystallises in prisms or tables containing $C^{14}H^{10}O^8 \cdot 3H^2O$, which gradually turn yellow on exposure to the air; it gives off its water at 100°, is converted at 105° into a viscid tenacious mass, melts and partly sublimes at 148°; when heated on platinum foil it gives off an odour of vanilla. It dissolves easily in water and alcohol, very slightly in ether; colours ferric chloride bluish-violet; reduces ammoniacal silver solution slowly, Fehling's copper solution not at all even when heated.

Isopinic acid crystallises in nodules, also containing 3 mol. water, more soluble in water than opinic acid, easily soluble in alcohol, sparingly in ether. It gives off $\frac{3}{4}$ of its water of crystallisation over oil of vitriol, the rest at 100°; sublimes at 130°, begins to melt at 144°, melts completely at 148°, and emits an odour of vanilla when more strongly heated. In its original state it forms a blue solution with ferric chloride, but after fusion a green solution. It is a more powerful reducing agent than opinic acid, decomposing Fehling's solution when heated.

Liechti regards isopinic acid as identical with Matthiessen and Foster's hypogallic acid (iii. 239), which, according to his view, is not isomeric with oxysalicic acid.

OPIUM-BASES. Cl. Bernard (*Arch. Pharm.* [2] cxix. 240) divides the opium-bases, according to their observed action upon animals, into the three following classes, in each of which the most active base is placed first:

<i>Narcotic.</i>	<i>Exciting.</i>	<i>Poisonous.</i>
Narceine.	Thebaine.	Thebaine.
Morphine.	Papaverine.	Codeine.
Codeine.	Narceine.	Papaverine.
	Codeine.	Narceine.
	Morphine.	Morphine.
	Narceine.	Narceine.

On the physiological action of the opium-bases, see also Baxt (*Wien. Akad. Ber.* lvi. [2] 189; *Jahresb.* 1867, p. 625). For their solubilities and reactions, see ALKALOIDS (p. 87).

Several new bases have lately been obtained by Hesse (*Ann. Ch. Pharm.* cliii. 47) from the aqueous extract of opium—namely, *codamine*, $C^{19}H^{23}NO^2$, *lanthopine*, $C^{21}H^{25}NO^4$, *laudanine*, $C^{20}H^{24}NO^3$, and *meconidine*, $C^{21}H^{25}NO^4$. To separate them, the aqueous extract is precipitated with excess of lime or sodium carbonate; the liquid separated from the precipitate is agitated with ether; and the ethereal extract is mixed with acetic acid. After removing the ether, the acid solution is poured in a thin stream into moderately dilute potash- or soda-ley, the alkali being kept in excess, and the liquid stirred to prevent the caking together of a resinous precipitate (P) containing papaverine and thebaine. This precipitate is separated after 24 hours, and the filtrate, after supersaturation with hydrochloric acid, is immediately mixed with ammonia, whereby a flocculent precipitate is formed, then with chloroform without previous filtration, and the chloroform solution is treated with acetic acid. After removal of the chloroform, the acid solution is exactly neutralised with ammonia, whereby a reddish, resinous, quickly crystallising precipitate is formed, containing lanthopine. After 24 hours the yellowish solution is decanted, filtered, and added to the small quantity of potash-ley sufficient to precipitate it (this quantity must, however, be large enough to decompose all the acetate of ammonia in the liquid, and leave an excess sufficient to precipitate the bases). The potash-solution thus obtained is turbid from separated codeine, which may be completely removed by agitating the liquid with ether, as it is much more soluble in ether than the other bases; the latter, indeed, are not taken up by the ether till they have been set free by sal-ammoniac. The ethereal solution left to evaporate very slowly in a tall narrow cylinder yields in the first place a crystallisation of laudanine; and on diluting the mother-liquor with a little ether, washing with bicarbonate of soda, and leaving the ether to evaporate, crystals of codamine are very soon deposited. The mother-liquor contains meconidine, together with another base, α , not yet examined.

These bases and their salts are described in their alphabetical places. The quantities of them contained in opium are extremely small. A sample of Turkey opium containing 8.3 p. c. morphine yielded only 0.0058 p. c. lanthopine, 0.0052 p. c. laudanine, and 0.0033 p. c. codamine.

Codamine and laudanine form a homologous series with morphine and codeine:

$C^{17}H^{21}NO^3$	$C^{18}H^{22}NO^4$	$C^{19}H^{23}NO^3$	$C^{20}H^{24}NO^3$
Morphine.	Codeine.	Codamine.	Laudanine.

Pseudomorphine, $C^{17}H^{21}NO^4$ (iii. 1051), and apomorphine, $C^{17}H^{19}NO^2$ (p. 839), are lateral members of this series.

A second group of homologous opium-bases includes papaverine, $C^{21}H^{27}NO^4$, and lanthopine, $C^{22}H^{28}NO^4$, to which are related cryptopine, $C^{22}H^{28}NO^4$, and the isomeric bases rhœadine and rhœagenine, $C^{21}H^{27}NO^6$. Rhœagenine, the salts of which resemble those of papaverine in many respects, may indeed be regarded as dioxypapaverine, and cryptopine as oxylanthopine. Meconidine, $C^{21}H^{25}NO^4$, contains 2 at. hydrogen more than papaverine, and is homologous with sanguinarine or chelerythrine, $C^{21}H^{27}NO^4$ (v. 188), the alkaloid contained in the commoncelandine, also a papaveraceous plant (Hesse).

OPOPONAX. This resin fused with potassium hydrate is converted into proto-catechuic acid, a small quantity of pyrocatechin, and an acid precipitated by lead acetate, but not yet analysed (Hlasiwetz a. Barth, *Jahresb.* 1866, p. 630).

OPOSIN. An albuminous substance obtained, together with syntonin, from muscular flesh. It is found in the expressed flesh-juice, and appears to exist more abundantly in mutton than in beef. The solution of well-washed syntonin in water containing hydrochloric acid is not precipitated by mercuric chloride; but that of oposin gives a precipitate both with mercuric chloride and with strong hydrochloric acid. The platinum salts of both these bodies contain from 10 to 11 p. c. platinum (Commalle, *J. Pharm.* [4] iv. 108).

ORANGE-TREE. T. E. Thorpe (*Chem. Soc. J.* [2] vi. 515) has analysed the ash of the root, stem, branches, and fruit of a diseased orange-tree from the Balearic Isles, where the orange-trees have lately suffered from a very formidable malady. The ash of all parts of the diseased tree was found to differ considerably from that of the corresponding parts of a healthy orange-tree, exhibiting especially an increased proportion of lime, and a diminished proportion of phosphoric acid, excepting in the fruit, in which there was a large excess of potash. It is not known whether these

deviations have any connection with the origin of the disease, or whether they are merely consequences of it.

ORCHELLA WEED. Two varieties of orchella weed are used for the preparation of archil or orchil, namely *Rochella tinctoria*, imported from the Cape de Verde islands and from Chile, and *Rochella fuciformis*, imported from Angola, Zanzibar, Madagascar, and Lima. The former treated with milk of lime yields lecanoric acid (with which Stenhouse's α and β orsellic acids have been shown to be identical, both by himself and by Gerhardt); the latter was found by Hesse to yield erythric acid (Stenhouse, *Chem. Soc. J.* [2] v. 221).

For estimating the amount of colouring matter in these and other lichens, Stenhouse formerly gave the two following methods: (1) The lichen is exhausted with milk of lime; the clear liquor is precipitated with acetic acid; and the precipitated colouring matter is collected on a weighed filter, dried at the ordinary temperature, and weighed. —(2) The comminuted lichen (100 grains) having been macerated with milk of lime till all the colouring matter is extracted, a titrated solution of calcium hypochlorite is gradually added to the clear filtrate, whereby a blood-red colour is at first produced, which shortly disappears, leaving the liquid of a deep yellow colour. The addition of the hypochlorite must be continued, at last by drops, as long as these changes of colour continue to be produced. The number of measures of the hypochlorite solution required to destroy the colouring matter determines the amount of it in the solution (*Phil. Trans.* 1848). Stenhouse now modifies this last process by exhausting the lichen with weak caustic soda, and using a standard solution of sodium hypochlorite instead of the corresponding calcium salt. The advantage of this modification of the method is that the liquor remains quite transparent during the entire process (*Chem. Soc. J.* [2] v. 226).

ORCIN. $C^7H^6O^2 = C^7H^6(II^2O^2)$.—This substance appears to have the constitution of a diatomic phenol, inasmuch as it is produced by abstraction of CO^2 from orsellinic acid, $C^8H^6O^4$ (by boiling it with baryta-water), just as oxyphenol or pyrocatechin, $C^6H^4O^2$, is produced from oxysalicylic acid, $C^7H^6O^4$.

Respecting the preparation of orcin (and erythrin) from erythrin, see ERYTHRIN (p. 582). The nearly colourless solution of orcin in benzol is agitated in a glass flask with about one-tenth of its bulk of water, which extracts the orcin from the benzol. The aqueous solution thus obtained generally deposits crystals of orcin on cooling, and the whole of the orcin may be separated by sufficient concentration. It may be obtained colourless by a second treatment with benzol and recrystallisation from water (Stenhouse, *Chem. Soc. J.* [2] v. 223).

Orcin heated for some time above its boiling point remains liquid several hours after cooling, and at last solidifies suddenly, with evolution of heat. Vapour-density obs. = 4.20; calc. = 4.28. Orcin dissolves without alteration in caustic potash; does not oxidise in contact with platinum-black; is not attacked by concentrated hydriodic acid; when fused with phosphorus iodide it gives off hydriodic acid, and forms a resin soluble in alkalis. Aqueous orcin dissolves the hydrates of barium and calcium in considerable quantity, the solutions, when heated or mixed with alcohol, yielding precipitates of indefinite composition which turn red on exposure to the air (De Luynes, *Ann. Ch. Phys.* [4] vi. 184; *Jahresb.* 1865, p. 591). In contact with sulphur chloride, orcin is converted, with evolution of hydrochloric acid, into a sulphur-yellow amorphous compound, insoluble in water, alcohol, benzol, and carbon bisulphide, but dissolving with partial decomposition in alkalis (Stenhouse).

Anhydrous orcin heated in ammonia gas melts and absorbs a considerable quantity. A solution of orcin in 3 or 4 pts. ether saturated with ammonia, deposits on standing large octohedral crystals of orcin-ammonia, $C^7H^6O^2 \cdot NH^3$. This compound when quickly dried in a vacuum is colourless and inodorous, easily soluble in alcohol, sparingly in ether; it is not altered by dry oxygen, even when exposed to it for months, but on adding a little water it takes up oxygen and becomes coloured in a few hours; on exposure to the air it takes up water, gives off ammonia, and turns violet. It is likewise oxidised and coloured by permanganate of potassium, chromate of potassium or ammonium, and peroxide of barium, these compounds being reduced, and the products forming lakes with the colouring matter. It also reduces arsenic acid and ammoniacal solution of cupric sulphate. When orcin is heated to 45° – 50° with aqueous ammonia, the surface of the liquid being constantly renewed and the ammonia replaced as it evaporates, the solution in about a week becomes viscid and violet coloured, and when filtered yields a violet liquid, which leaves on evaporation a violet resinous mass resembling orcin, and a brown precipitate, the alcoholic solution of which deposits colourless crystals covered with a brown powder (De Luynes, *loc. cit.*; also *Zeitschr. f. Chem.* [2] iv. 700).

Orcin unites directly with *picric acid*, forming the compound $C^3H^3(NO^3)_3O$, the aqueous solution of which dyes silk yellow, like free picric acid. With *pyrogallia acid* it forms a compound which crystallises in large laminae, and blackens slightly on exposure to the air. Aqueous solutions of orcin and *nicotine* when mixed deposit a compound of the two in oily drops, which dissolve in excess of nicotine. An aqueous solution of orcin dissolves *rosaniline*, with deep red colour. Orcin deliquesces in gaseous *ethylene oxide*, 1 gram of it absorbing more than 400 c. c. of the gas, which it does not give up again in contact with solid potash. On adding *common salt* in excess to an aqueous solution of orcin, the two combine and form a crystalline precipitate, which fills the entire liquid (De Luynes, *Zeitschr. f. Chem.* [2] iv. 703).

Diacetyl-orcin, $C^{11}H^{10}O^4 = C^3H(C^2H^3O)^2O^2$, is formed by the action of acetyl chloride on pulverised orcin, and remains, on evaporating its ethereal solution, as an oily body, which crystallises in needles when cooled below 25° . It melts at 25° , then remains liquid for a long time even if cooled to 0° , and solidifies suddenly by contact with a crystal. It is nearly insoluble in water, very soluble in alcohol and ether, makes a transient greasy stain on paper, evaporates when heated, leaving a small quantity of charcoal, and is resolved by boiling with alkalis into orcin and acetic acid. It acquires a transient red colour in contact with chloride of lime, and is converted in an atmosphere of ammonia into ammonium acetate and orcin. *Dibutryl orcin*, $C^8H^4(C^4H^7O)^2O^2$, formed by the action of butyryl chloride on fused orcin, is a colourless uncrystallisable liquid, which reacts like the acetyl compound. *Dibenzoyl orcin*, $C^8H^4(C^6H^5O)^2O^2$, crystallises in hard colourless needles, inodorous, but having a sweet taste; melts at 40° , decomposes at a higher temperature, is insoluble in water, but dissolves easily in alcohol and ether, and is decomposed, by boiling with alkalis, into orcin and benzoic acid (De Luynes).

Alcoholic Orcins.—*Methyl-orcin*, $C^3H^3(CH^3O)^2$, *ethyl-orcin*, $C^3H^3(C^2H^5O)^2$, and *amyl-orcin*, $C^3H^3(C^4H^9O)^2$, are produced by heating the corresponding alcoholic iodides with orcin in equivalent proportions. The first two are syrupy liquids; *amyl-orcin* crystallises in needles. *Diethyl-orcin*, $C^8H^8(C^2H^5O)^2O^2$, and *diamyl-orcin*, $C^8H^8(C^4H^9O)^2O^2$, are formed by heating 1 mol. orcin with 2 mol. of the alcoholic iodide and potash. Both are syrupy; the ethyl-compound distils without decomposition between 240° and 250° . Lastly, when a large excess of the alcoholic iodide is used, together with potash, the compounds $C^3H^3(CH^3O)^3O^2$, $C^3H^3(C^2H^5O)^3O^2$, and $C^3H^3(C^4H^9O)^3O^2$ are produced. *Trimethyl-orcin* is liquid, and boils without decomposition at about 250° under ordinary pressure; *triethyl-orcin* at 265° . It has not yet been found possible to reconvert either of these compounds into orcin and the original alcohol. *Diacetyl-orcin* treated with sodium ethylate forms, together with sodium hydrate and ethyl acetate, a body soluble in water, but apparently not consisting of orcin (De Luynes a. Lionet, *Compt. rend.* lxx. 213).

Trinitro-orcinic acid, $C^3H^3(NO^3)_3O^2$, is produced by gradually adding orcin to strong nitric acid cooled by a freezing mixture, and dropping the resulting brown solution into strong sulphuric acid also cooled to a low temperature. On pouring the yellow pasty mixture thus produced into a considerable quantity of cold water, the trinitro-orcinic acid separates as a bright yellow crystalline powder, which may be purified by one or two crystallisations from boiling water. It then forms large yellow needles, soluble in alcohol, slightly soluble in cold water, readily in hot water. It is a strong acid, much resembling picric acid, but differs from the latter by the solubility of its salts. The *potassium salt*, $C^3H^3(NO^3)_3O^2K^2$, prepared by dissolving the acid in a warm and rather strong solution of potassium carbonate, solidifies on cooling to a mass of fine needles of a deep orange colour. The *sodium*, *calcium*, and *silver salts* crystallise well, and are moderately soluble in water; the *lead salt* is much less soluble.

Beta-orcin, $C^8H^8O^2$, treated with nitric and sulphuric acids as above, yields a yellow substance which appears to be the corresponding nitro-compound of beta-orcin. Resorcin yields *trinitroresorcinic acid*, $C^6H^3(NO^3)_3O^2$, which crystallises readily, is of a much paler colour than trinitro-orcinic acid, but resembles it closely in most respects, and likewise forms crystalline salts (Stenhouse, *Chem. News*, xxii. 98; Aug. 26, 1870).

ORNITHITE. Tricalcic phosphate, $(PO^4)^3Ca^2 + 2H^2O$, found in monoclinic crystals in Sombbrero guano (Julien, *Sill. Am. J.* [2] xl. 367).

ORSELLINIC ACID. $C^8H^8O^4$ —Menschutkin (*Bull. Soc. Chim.* [2] ii. 424) regards this acid as diatomic, and represents its formation from *lecanoric acid*, *erythrin*, and *picro-erythrin*, by the following equations:

ORTHO-CARBONATES—OSTEOLITE.

Grimaux, on the other hand (*ibid.* iii. 410), regards orsellinic acid as monobasic, but triatomic, as represented by the formula $\left\{ \begin{array}{c} \text{C}^8\text{H}^6\text{O} \\ \text{H}^3 \end{array} \right\} \text{O}^3$ (inasmuch as it is converted by loss of CO^2 into diatomic orcin), and alters Menshutkin's formula of the lichen-constituents as follows:

Ethyl Orsellinate, $\text{C}^8\text{H}^6\text{O}^4 \cdot \text{C}^2\text{H}^5$, is most conveniently prepared by digesting erythrin with 8 pts. absolute alcohol, distilling, boiling the viscous residue (consisting of ethyl orsellinate, picro-erythrin, and resin) with water, and the portion which crystallises from the aqueous solution with benzol, which dissolves the ethyl orsellinate and deposits it in crystals. *Ethyl di-iodorsellinate*, $\text{C}^8\text{H}^6\text{I}^2\text{O}^4 \cdot \text{C}^2\text{H}^5$, is formed by mixing a cold-saturated aqueous solution of ethyl orsellinate with a very dilute solution of iodine chloride containing excess of iodine, in quantity not sufficient for complete precipitation. The precipitate, washed with cold water and several times recrystallised from carbon bisulphide and alcohol, forms small needles soluble in benzol, carbon bisulphide, and hot alcohol, slightly soluble in boiling water. Heated above 100° , they melt and decompose, with liberation of iodine. *Methyl di-iodorsellinate*, $\text{C}^8\text{H}^6\text{I}^2\text{O}^4 \cdot \text{CH}^3$, prepared in a similar manner, likewise crystallises in needles (Stenhouse, *Chem. Soc. J.* [2] v. 224).

ORTHO-CARBONATES. See CARBONATES (i. 778 ; iv. 238).

ORTHO-FORMATES. See FORMATES (p. 622).

OSMIUM. Experiments by Wöhler (*Ann. Ch. Pharm. Suppl.* iv. 253) seem to show that the black oxide produced by fusing metallic osmium with potash is neither the trioxide, nor, as commonly supposed, the tetroxide (iv. 246), but an intermediate oxide, inasmuch as it dissolves in water with deep reddish-yellow colour (without perceptible evolution of gas), and is resolved by addition of acids into a black oxide and the tetroxide OsO^4 . Such a solution concentrated to one-fourth, and left to cool out of contact with the air, deposits crystallised violet potassium osmite. On passing carbon dioxide through the yellow liquid decanted from the crystals, it first becomes colourless, then violet, with liberation of osmium tetroxide, and deposition of a greyish-violet precipitate. On treating this precipitate with water, a small quantity of brown oxide is separated, and a violet solution formed, from which nitric acid again precipitates black oxide, with formation of osmic acid. The solution of the violet crystals reacts with carbon dioxide in the same manner.

When sublimed osmium tetroxide is dissolved in excess of potash, and the deep yellow-red liquid is evaporated over potassium hydrate, opaque nodular groups of crystals are formed, soluble in water with reddish-yellow colour (without a trace of potassium osmite), and nitric acid added to the concentrated solution throws down, first white tetroxide, and then black oxide. The black oxide forms with concentrated hydrochloric acid, first a purple solution, which afterwards becomes yellow-brown, green, and when heated brownish-yellow, and is coloured pure yellow by sulphurous acid, without separation of metal, even at the boiling heat. Zinc precipitates osmium from this solution in black flocks.

OSTEOLITE. In osteolite from Eichen in the Wetterau, Church (*Chem. News*, xvi. 150) found 87.25 p. c. $(\text{PO})^4\text{Ca}^2$, 6.70 CO^2Ca , 4.92 CaF^2 , and 2.34 water: hence he concludes that it consists of apatite, more or less altered.

OXALIC ACID. $\text{C}^2\text{H}^2\text{O}^4 = \begin{array}{c} \text{COOH} \\ | \\ \text{COOH} \end{array}$ —This acid is formed by reduction of

carbonic acid. When dry carbon dioxide is passed into a flask containing metallic sodium and fine sand, and heated to about the boiling point of mercury, the mixture of sand and sodium being well stirred, sodium oxalate is produced by direct combination: $\text{Na}^2 + 2\text{CO}^2 = \text{C}^2\text{O}^4\text{Na}^2$. This product, spread out upon a plate to oxidise the remaining sodium, and then digested with water, yields a solution which, after neutralisation with acetic acid, forms with calcium chloride the characteristic precipitate of calcium oxalate (Drechsel, *Zeitschr. f. Chem.* [2] iv. 120). Oxalic acid is also formed by oxidising acetic acid in alkaline solution with potassium permanganate; $\text{C}^2\text{H}^3\text{O}^2 + \text{O}^2 = \text{C}^2\text{H}^2\text{O}^4 + \text{H}^2\text{O}$ (Lossen, *Ann. Ch. Pharm.* cxlviii. 174).

On the occurrence of oxalates in urine and urinary sediments, see Neubauer (*Zeitschr. f. Chem.* [2] v. 30).

By *potassium permanganate*, in acid solution, and likewise, though slowly, in alkaline solution, oxalic acid is oxidised to water and carbon dioxide (Berthelot). Harcourt (*Chem. Soc. J.* [2] v. 460) gives for this reaction in acid solution the equation:

The oxidation of oxalic to carbonic acid takes place quickly at the positive pole of a voltaic circuit. A neutral solution of potassium oxalate gives off at the positive pole, first carbon dioxide, then oxygen; an alkaline solution, first oxygen, then carbon dioxide (Burgoin, *Ann. Ch. Phys.* [4] xiv. 157).

Oxalic acid heated with concentrated aqueous *hydriodic acid* is resolved into carbon dioxide, carbon monoxide, and water (Berthelot).

The crystalline forms of several metallic oxalates have been examined by J. Loschmidt (*Wien. Akad. Ber.* li. [2] 7, 384; *Jahresh.* 1865, p. 374).

Calcium oxalate may be obtained in fine crystals by placing a layer of aqueous oxalic acid above a denser solution of sugar-lime (E. Monier, *Compt. rend.* lxi. 1013). Both *calcium oxalate* and *lead oxalate* dissolve in the saccharine juice of beet (Scheibler, *Zeitschr. f. Chem.* [2] i. 62).

Manganous oxalate precipitated by adding a cold concentrated aqueous solution of oxalic acid to manganous sulphate, or ammonium oxalate to excess of manganous sulphate, has the composition $\text{C}^2\text{O}^4\text{Mn} + 3\text{H}^2\text{O}$; in the latter case the precipitation of the oxalic acid is complete (How, *Chem. News*, xix. 41).

Silver oxalate is commonly said to retain 2 p. c. water with great obstinacy (*Gmelin's Handbook*, ix. 169). According to Thudichum a. Wanklyn, however, this is not the case, the salt dried in a vacuum over sulphuric acid, and finally at 110° , being quite anhydrous (*Chem. Soc. J.* [2] vii. 294).

An *oxalato-chloride of strontium*, $\text{C}^2\text{SrO}^4.\text{SrCl} + 6\text{H}^2\text{O}$, is obtained in rhombic crystals by prolonged contact of a perfectly saturated solution of strontium chloride with washed and still moist strontium oxalate. It gives off 4 mol. water at 100° , is not altered by alcohol, but is resolved by water into its constituent salts. When the crystals of this salt are covered with two or three times their weight of a saturated solution of strontium chloride, and a solution of the same salt diluted with an equal bulk of water is gradually added at intervals of two or three hours, the rhombic crystals disappear, and are succeeded by prismatic crystals of the salt $3\text{C}^2\text{SrO}^4.\text{SrCl}^2 + 16\text{H}^2\text{O}$. This latter salt is also formed when the rhombic crystals are left for some time in an atmosphere saturated with aqueous vapour. In a similar manner may be obtained the double calcium salt, $\text{C}^2\text{CaO}^4.\text{CaCl}^2 + 7\text{H}^2\text{O}$, described by Fritzsche (iv. 255), and corresponding oxalato-chlorides of barium and magnesium (G. Rainey, *Proc. Roy. Soc.* xiv. 144).

Neutral thallium oxalate, $\text{C}^2\text{Tl}^2\text{O}^4 + 4\text{H}^2\text{O}$, forms short prismatic crystals. An acid salt, $\text{C}^2\text{H}^2\text{TlO}^8 + 2\text{H}^2\text{O}$, crystallises in large laminae from a solution mixed with a considerable excess of oxalic acid (Carstanjen, *Jahresh.* 1867, p. 281).

Ethyl oxalate heated with sodium ethylate is converted into ethyl carbonate, with evolution of carbon monoxide, and simultaneous formation of sodium oxalate, a small quantity of sodium formate, and the sodium salts of complex organic acids (Löwig's 'nigric acids') (Geuther, *Zeitschr. f. Chem.* [2] iv. 656. Cranston a. Dittmar, *Chem. Soc. J.* [2] vii. 441). In the production of ethylic carbonate from ethylic oxalate, by the action of sodium (iv. 270), sodium ethylate appears to be formed in the first instance, which then reacts as above (Geuther).

OXALO-HYDROXAMIC ACID. $\text{C}^2\text{H}^4\text{N}^2\text{O}^4$.—An acid produced by the action of hydroxylamine on ethyl oxalate. (See *HYDROXYLAMINE*, p. 724.)

OXAMIC ACID. $C^2H^2NO^3$.—According to L. C. de Coppet (*Ann. Ch. Pharm.* cxxxvii. 105), ammonium oxamate is produced when ammonia gas in excess is passed into a cooled alcoholic solution of ethyl oxalate:

Phenyl-oxamic or *Oxanilic Acid*. $C^2H^2(C^6H^5)NO^3$.—In preparing this acid by fusing aniline with a large excess of oxalic acid, it is best to exhaust the fused mass with water, boil the solution with excess of lime, supersaturate the filtrate with sulphuric acid, and agitate it with ether, which takes up the oxanilic acid. When nitrous acid vapour is passed into an alcoholic solution of this acid, the only products formed, besides nitrogen gas, are phenol and oxalic acid. Hence the nitrogen-atom appears to connect the two carbon-residues in the acid, and the latter may be represented by the formula $C^6H^5-NH-CO-CO^2H$ (Claus, *Zeitschr. f. Chem.* [2] iv. 158).

OXAMIDE. $\left. \begin{matrix} C^2O^2 \\ H^1 \end{matrix} \right\} N^2$, is formed when cyanogen gas is passed into strong aqueous hydrochloric acid: $2CN + 2H^2O = C^2H^2N^2O^2$. The liquid after twelve hours deposits crystals of oxamide, while a small quantity of ammonium oxalate remains in solution. Strong hydriodic acid also quickly yields oxamide when cyanogen gas is passed into it, iodine being also separated, and the solution retaining hydrocyanic acid and ammonium iodide (Schmitt a. Glutz, *Deut. chem. Ges. Ber.* 1868, p. 66).

A compound isomeric with oxamide is produced by heating urea and dry formic acid (prepared by the action of hydrogen sulphide on lead formate) to 100° for several days in a flask with upright condenser: $CH^1N^2O + CH^2O^2 = H^2O + C^2H^2N^2O^2$ (Scheitz, Marsh, a. Geuther, *Zeitschr. f. Chem* [2] iv. 300).

Oxamide heated to 125° with formic acid is converted into ammonium oxalate. Heated to 200° with benzoic anhydride it yields benzamide. Acetic anhydride does not act upon it at 160° . Heated with zinc and dilute acetic acid it is converted into ammonium glycollate (Scheitz, Marsh, a. Geuther). When an intimate mixture of 5 mol. oxamide and 2 mol. phosphorus pentachloride is slowly heated in a small retort, an orange-yellow sublimate is formed (probably a sulphhydrate of cyanogen), and a mixture of hydrogen sulphide and cyanogen is given off (L. Henry, *Deut. chem. Ges. Ber.* 1869, p. 305).

A compound of oxamide with cupric oxide, $2C^2H^2N^2O^2 \cdot CuO$, previously obtained by Toussaint (*Ueber die Oxaminsäure, Inauguraldiss. Göttingen*, 1861), is formed by adding a hot solution of oxamide to neutral cupric acetate. It is a light, loose, very hygroscopic powder, decomposed by the stronger mineral acids (Scheitz, Marsh, a. Geuther). Dessaignes obtained a compound of oxamide with mercuric oxide, containing $2C^2H^2N^2O^2 \cdot HgO$ (iv. 284).

The compound $C^2H^2N^2O^2$, produced by the action of cyanogen on moist aldehyde, may be regarded as *ethylidene-dioxamide*,

OXAMYLAMMONIUM HYDRATE, $\left. \begin{matrix} H^3 \\ C^2H^1O^2OH \end{matrix} \right\} N \cdot OH$, is produced by treating the chlorhydrin of amyl-glycol with ammonia, and the resulting chloride with moist silver oxide (Wurtz). See CHOLINE (p. 449).

OXANTHRACENE. See ANTHRACENE.

OXINDOL. See INDOL.

OXETHYL-GLYCOLLYL-ALLOPHANIC ACID. $C^2H^2O^2N^2O^3$ (Saytzeff, *Anh. Ch. Pharm.* cxxxiii. 329).—The potassium salt of this acid is produced by heating potassium cyanate with ethyl chloracetate and alcohol:

The liquid decanted from potassium chloride, concentrated to one-tenth of its volume, and mixed with ether, separates into two layers, the upper of which contains ethyl allophanate (formed by the action of the potassium cyanate on the alcohol), while the lower, which is semicrystalline, consists mainly of potassium oxethyl-glycollyl-allophanate, which may be dissolved out by water; and in mixing the aqueous solution with dilute sulphuric acid, oxethyl-glycollyl-allophanic acid separates in crystals. This acid, purified by conversion into a lead salt and separation

by hydrogen sulphide, crystallises in rhombic tables sparingly soluble in cold water, alcohol, and ether. Its *alkali-metal salts* are very soluble and crystallisable. The *lead salt*, $(C^6H^5N^2O^3)^2Pb$, forms sparingly soluble needles; the *barium salt*, $(C^6H^5N^2O^3)^2Ba$, microscopic rhombic tables; the *silver salt* is very soluble in water, and decomposes even when its solution is heated.

Oxethyl-glycollyl-allophanic acid gives off cyanic acid when heated, and is decomposed by boiling with strong potash-ley into glycollic acid, carbonic acid, alcohol, and ammonia:

It is not decomposed by nitric or nitrous acid. Strong sulphuric acid decomposes it with evolution of carbon dioxide. By boiling with dilute sulphuric acid it is converted into a new acid, which is likewise produced, together with oxethyl-glycollyl-allophanic acid, by the action of potassium cyanate on ethyl monochloracetate. This acid is soluble in ether, uncrystallisable, forms uncrystallisable salts, and is likewise converted into glycollic acid by boiling with potash.

OXYANILINE, $C^6H^5NO = C^6H^5-O-NH^2$, is produced by heating amidosalicylic acid mixed with pumice-powder:

When freed from a brown secondary product by means of alcohol containing acetic acid, it forms white needles, the aqueous solution of which quickly turns brown when left to itself, indigo-blue on addition of alkalis, and is decolorised again by acids. It reduces the oxides of the noble metals, forming a violet liquid. It unites with hydrochloric, hydrobromic, and hydriodic acids, forming salts which are stable only in presence of excess of acid (R. Schmitt, *Chem. Soc. J.* [2] ii. 124).

OXYBENZAMIDE, $C^6H^5NO^2 = C^6H^5(OH).CONH^2$.—Produced by boiling the aqueous solution of nitrate of diazobenzamide:

It crystallises in white prisms sparingly soluble in cold water, easily in boiling water, also in alcohol and ether. By boiling with aqueous potash it is converted into oxybenzoic acid: $C^6H^5NO^2 + H^2O = NH^3 + C^6H^5O^3$, whereas its isomeride, amidobenzoic acid, $C^6H^5NH^2.CO^2H$ (formed by reduction of nitrobenzoic acid), is not decomposed in the same manner, but only by fusion with potassium hydrate, being then resolved into carbon dioxide and aniline: $C^6H^5NO^2 = CO^2 + C^6H^5N$. Moreover, oxybenzamide is converted by nitrous acid into a diazo-compound, whereas amidobenzoic acid similarly treated is transformed into oxybenzoic acid. In like manner, paraoxybenzamide (oxydiacetylamide) differs from amido-paraoxybenzoic acid, and metaoxybenzamide (salicylamide) from amido-metaoxybenzoic (anthranilic) acid (Griess, *Zeitschr. f. Chem.* [2] ii. 1).

OXYBENZOIC ACID, $C^6H^5O^3 = C^6H^5(OH).CO^2H$.—In preparing this acid by the action of nitrous acid on amidobenzoic (oxybenzamic) acid (iv. 200), Gräbe a. Schultzen (*Ann. Ch. Pharm.* cxlii. 350) neutralise the boiling solution of amidobenzoic acid in 100 pts. water, after the action of the nitrous acid is complete, with levigated chalk, to prevent loss by volatilisation with the aqueous vapour, decolorise the resulting calcium salt by repeated treatment with animal charcoal, and decompose it with hydrochloric acid. Oxybenzoic acid is more advantageously prepared by fusing potassium sulphobenzoate (benzene-sulphate, benzyl-sulphite) with potassium hydrate:

Benzoic acid (100 grms.) is converted into sulphobenzoic acid by treatment with vapour of sulphur anhydride; the product is made to drop through a narrow funnel into cold water; the liquid filtered from undecomposed benzoic acid is neutralised with milk of lime; the filtrate, together with the solution obtained by boiling the residual gypsum, is concentrated, and precipitated while warm with potassium carbonate; and the filtered solution of potassium sulphobenzoate is evaporated to dryness. This salt is then fused with $2\frac{1}{2}$ times its weight of potassium hydrate and a little water in a silver basin; the fused mass is saturated with sulphuric acid and agitated with ether; the ethereal solution evaporated; and the residual oxybenzoic acid, after being recrystallised once or twice, with addition of animal charcoal, is finally freed from traces of benzoic acid by treatment with carbon bisulphide. By this process 100 pts. benzoic acid yield from 70 to 75 pts. oxybenzoic acid. A small quantity of a

syrupy acid, probably oxysalicylic acid, $C^7H^6O^4$ (protocatechuic acid, according to Senhofer), is formed at the same time (L. Barth, *Ann. Ch. Pharm.* cxlviii. 30; *Zeitschr. f. Chem.* [2] v. 23). Amidobenzoic acid heated with potassium hydrate yields only small quantities of oxybenzoic acid: $C^7H^5(NH^2)O^2 + H^2O = NH^3 + C^7H^6O^3$ (Barth).

Ammonium Oxybenzoate, $C^7H^6O^3 \cdot NH^4$, crystallises in tufts of needles easily soluble in cold water, giving off part of their ammonia when dried in a vacuum. The *barium salt*, $(C^7H^5O^3)^2Ba$, obtained by saturating the acid with barium carbonate, is uncrystallisable. Its solution mixed with excess of baryta does not yield a salt containing $C^7H^4O^3Ba$. The *cadmium salt*, $(C^7H^5O^3)^2Cd$, forms nodular groups of indistinct needles. The *copper salt*, $(C^7H^5O^3)^2Cu + H^2O$ (air-dried), crystallises in green needles.

Oxybenzoic Ethers.—*Ethyl Oxybenzoate*, $C^8H^7(OH) \cdot CO^2C^2H^5$, is formed by passing hydrochloric acid gas into the alcoholic solution of the acid, and precipitating with water. It crystallises from ether and from hot water in hard tables, melting at 72° – 74° (Gräbe a. Schultzen); in broad laminae and scales melting at 67° (Barth). It distils at higher temperatures, is nearly insoluble in cold water, more soluble in hot water, also in alcohol and ether. By strong soda-ley in the cold it is converted into a white crystalline pulp of *ethylic sodium-oxybenzoate*, $C^8H^7(ONa) \cdot CO^2C^2H^5$, which is resolved into alcohol and sodium oxybenzoate by boiling its aqueous solution, and reconverted into ethylic oxybenzoate by boiling with hydrochloric acid (Gräbe a. Schultzen). According to Rosenthal (*Zeitschr. f. Chem.* [2] v. 627), ethylic oxybenzoate treated with sodium and carbon dioxide is converted into ethyl-oxybenzoic acid, $C^8H^7(OC^2H^5) \cdot CO^2H$.

Methyl-oxybenzoic Acid, $C^8H^7(OCH^3) \cdot CO^2H$.—The ethylic ether of this acid is produced by heating the ethylic ether of sodium-oxybenzoic acid with methyl iodide to 140° :

The acid produced from this ether by boiling with potash may be more easily prepared by heating 1 mol. oxybenzoic acid to 140° with 2 mol. potassium hydrate and 1 mol. methyl iodide, and decomposing the resulting methylic ether of methyl-oxybenzoic acid with potash; or, according to Körner (*Bull. Acad. Belg.* [2] xxiv. 155), by the action of carbon dioxide and sodium on methyl monobromophenate, $C^8H^4BrO \cdot CH^3$. It crystallises from water in long needles, slightly soluble in cold, easily in hot water, alcohol, and ether, melts at 96° , and sublimes without decomposition. Its *potassium* and *ammonium salts* are easily soluble and crystallisable; the *calcium salt*, $(C^8H^4O^3)^2Ca + H^2O$, separates from the concentrated solution in needles easily soluble in hot water. The *silver salt*, $C^8H^4O^3Ag$, is a white precipitate, which crystallises from warm water in long needles.

Dioxybenzoic acid, $C^7H^6O^4$ or $C^7H^5(OH)^2 \cdot CO^2H$, identical with protocatechuic acid, is produced by converting oxybenzoic acid into sulphoxybenzoic acid, $C^7H^5SO^3$, and fusing the potassium salt of the latter with potash (Barth).

Sulphoxybenzoic Acid, $C^7H^5SO^3 = C^7H^5O^3 \cdot SO^2H$ (Senhofer, *Ann. Ch. Pharm.* clii. 102).—Produced by passing vapour of sulphuric anhydride over oxybenzoic acid. On diluting the product with 10 or 12 pts. of water, removing unaltered oxybenzoic acid by repeated agitation with ether, precipitating the sulphuric acid with a slight excess of lead carbonate, mixing the filtrate with basic lead acetate, decomposing the washed precipitate with hydrogen sulphide, concentrating the filtrate strongly on the water-bath, and leaving it to itself for some time, sulphonybenzoic acid separates in dingy yellow crusts; it may be purified by repeated treatment, after drying, with a mixture of 1 pt. alcohol and 2 pts. ether, in which the pure acid slowly dissolves. By recrystallisation from water the acid is obtained in siskin-green needles, which retain $1\frac{1}{2}$ mol. H^2O when dried over sulphuric acid, give it off at 160° , and melt to a black pasty mass at 208° . It is deliquescent, very soluble in alcohol, nearly insoluble in ether; forms with ferric chloride a wine-red liquid, which is decolorised by sodium carbonate, and precipitated by basic, but not by neutral acetate of lead. The impure acid quickly becomes moist in contact with the air; but the pure acid is much less hygroscopic.

Barium Sulphoxybenzoate, $C^7H^4SO^3Ba$, forms colourless transparent prisms, which become opaque and friable on exposure to the air, and are somewhat sparingly soluble in water; the air-dried salt gives off 20.81 p. c. water at 168° ; calc. for $\frac{1}{2}H^2O$, 20.36 p. c. The *acid cadmium salt*, $(C^7H^4SO^3)^2Cd + 2H^2O$, forms straw-yellow crystalline nodules. The *lead salt*, $(C^7H^4SO^3)^2Pb$, is obtained as a bulky precipitate, which becomes somewhat denser when left in the liquid, and dries up to a pale red amorphous mass.

OXYBENZYL-COMPOUNDS. See TOLYL BISULPHIDE, under BENZENE HOMOLOGUES (p. 289).

OXYBUTYRIC ACID. $C^4H^5O^3$ (Morkownikoff, *Zeitschr. f. Chem.* [2] ii. 485; p. 620. Wislicenus, *Ann. Ch. Pharm.* cxlix. 205; *Zeitschr. f. Chem.* [2] iv. 680; p. 325).—The general formula of this acid may be resolved into five different structural formulae, three of which contain only a single chain of carbon-atoms, and may be regarded as derivatives of ordinary butyric acid:

while the remaining two may be derived from isobutyric acid:

Of these five oxybutyric acids two have been known for some time, namely α -oxyisobutyric and α -oxybutyric acids. The former is produced by the action of moist silver oxide on bromo-isobutyric acid (Morkownikoff, *Ann. Ch. Pharm.* cxvi. 339). The same structure belongs to Städeler's acetic acid, produced by the action of hydrocyanic and hydrochloric acids on acetone (p. 28):

and to Frankland & Duppa's dimethoxalic acid (iv. 274). Wurtz's butylactic acid (i. 688), obtained by oxidation of amylene glycol, is also, according to Friedel & Machuca (*ibid.* cxv. 279), identical with acetic acid. There are therefore four modes of formation of α -oxyisobutyric acid, all of which yield it in the crystalline state.

Another oxybutyric acid, also crystalline, was obtained by Friedel & Machuca (iv. 296), and by Naumann (*Ann. Ch. Pharm.* cxix. 115), by the action of silver oxide on normal bromobutyric acid. Now when hydrogen is replaced by chlorine or bromine in organic molecules already containing negative elements, the replacement generally takes place, at least in the first instance, in the immediate neighbourhood of the negative atoms already present: thus aldehydes are converted into acid chlorides; ethyl chloride, $CH^3 \cdot CH^2Cl$, into ethylidene dichloride, $CH^3 \cdot CHCl^2$; propionic acid, $CH^3 - CH^2 - COOH$, into α -chloropropionic acid, $CH^3 - CHCl - COOH$, &c. In like manner, normal butyric acid, $CH^3 - CH^2 - CH^2 - CO^2H$, acted upon by bromine will most probably yield a bromobutyric acid having the constitution $CH^3 - CH^2 - CHBr - CO^2H$, and this acid treated with silver oxide will be converted into α -oxybutyric acid, $CH^3 - CH^2 - CHOH - CO^2H$ (Wislicenus).

A third modification, viz. β -oxybutyric acid, which is non-crystalline, has recently been obtained by Morkownikoff and by Wislicenus:—1. From propylene-hydroxychloride, by converting that compound into the corresponding hydrocyanide by heating with potassium cyanide, and boiling the alcoholic solution of the product with caustic potash as long as ammonia continues to escape:

By acidulating the resulting solution with dilute sulphuric acid, agitating with ether, and evaporating the ethereal solution, β -oxybutyric acid is obtained in the form of a syrup, which may be purified by conversion into a lead salt, and separation with hydrogen sulphide (Morkownikoff).

2. By addition of hydrogen to acetyl-acetic acid, $C^2H^4(C^2H^3O)^2$:

The ethylic ether of acetyl-acetic acid (Geuther's ethyl-diacetic acid, p. 601) treated with water and sodium-amalgam is rapidly converted into the sodium salt of β -oxybutyric acid:

By slightly acidulating the alkaline liquid with hydrochloric acid, again neutralising with sodium carbonate, evaporating to a syrup, separating the sodium chloride which crystallises out, evaporating to dryness, digesting the residue with strong alcohol, and leaving the solution to cool, sodium β -oxybutyrate is obtained, and may be purified by repeated crystallisation from alcohol. By decomposing this sodium salt with sulphuric acid, agitating the solution with ether, and evaporating, β -oxybutyric acid is obtained as a slightly coloured viscid syrup, which quickly absorbs water from the air, and shows no tendency to crystallise. It volatilises somewhat readily with vapour of water, and decomposes when heated to 120° – 130° , yielding a thickish acid watery distillate, which on cooling deposits snow-white crystals, having the composition $\text{C}^4\text{H}^6\text{O}^4$, and exhibiting nearly the properties of crotonic acid obtained from ally cyanide (p. 509).

Sodium β -oxybutyrate, $\text{C}^4\text{H}^7\text{O}^3\text{Na}$, prepared as above forms anhydrous crusts made up of very soft sharply pointed crystals; it is soluble in water and in alcohol, and very deliquescent. The silver salt, $\text{C}^4\text{H}^7\text{O}^3\text{Ag}$, separates on mixing the solution of the sodium salt with silver nitrate, in snow-white, capillary, interlaced crystals. The calcium, copper, lead, and zinc salts, which are very soluble and amorphous, are obtained by boiling the acid with the corresponding carbonates (Wislicerus).

OXYCANNABIN. $\text{C}^8\text{H}^6\text{O}^2$.—A neutral crystalline substance obtained by the action of nitric acid on the resinous extract of Indian hemp. (See CANNABIS, p. 391.)

OXYCINNAMIC ACID. See CINNAMIC ACID (p. 470).

OXYDRACYLAMIC ACID. Syn. with Paramidobenzoic acid. See BENZOIC ACID (p. 320).

OXYGEN. *Preparation.*—1. Robbins (*Pharm. J. Trans.* [2] v. 456) recommends the decomposition of a pulverised mixture of 3 mol. barium peroxide and 1 mol. potassium dichromate with dilute sulphuric acid, whereby oxygen is abundantly evolved at ordinary temperatures.—2. Carlevaris (*Bull. Soc. Chim.* [2] iv. 255) heats a mixture of manganese dioxide and sand to incipient redness, whereby manganous silicate is produced, and half the oxygen of the manganese dioxide is evolved.—3. Chloride of lime in solution heated with a small quantity of recently prepared cobalt peroxide, is completely resolved into calcium chloride and oxygen (less easily by nickel peroxide). A concentrated solution of strong chloride of lime (35 p.c.) filtered to prevent frothing, yields, when heated with 0.1 to 0.5 p.c. cobalt peroxide, a volume of oxygen from 25 to 30 times as great as that of the liquid, and always rather more than the calculated quantity, probably in consequence of absorption of oxygen from the air. The remaining peroxide can always be used again. The same result is obtained by mixing the chloride of lime solution with a small quantity of an ordinary cobalt salt. It is probable that several peroxides of cobalt exist, and that the reaction depends upon the alternate formation and partial reduction of a higher oxide, or on the formation of a cobaltic or percobaltic hypochlorite, which is subsequently resolved into cobaltous chloride and oxygen (Fleitmann, *Ann. Ch. Pharm.* cxxxiv. 64). These observations have been confirmed by Reinsch (*Zeitschr. f. Chem.* [2] ii. 31), and similar observations have been made by Böttger, who likewise observes that cupric oxide and ferric hydrate decompose chloride of lime with violence, even at 60° , both remaining unaltered (*J. pr. Chem.* xcv. 309, 375; *Jahresb.* 1865, p. 119). Stolba (*ibid.* xcvi. 309) recommends that the chloride of lime in Fleitmann's process be used in the form of a stiff paste, with addition of a small quantity of cupric nitrate or chloride and a few small lumps of paraffin; by this means the frothing of the liquid is prevented. Winkler (*J. pr. Chem.* xcvi. 340) passes chlorine into thick milk of lime containing a few drops of solution of cobaltous chloride, and passes the evolved oxygen through a wash-bottle containing milk of lime, to remove a small quantity of chlorine with which it is mixed.

Maréchal and Tessié du Mothay prepare oxygen on the large scale by heating the manganates, permanganates, chromates, or ferrates (?) of the alkalis or alkaline earths in a current of steam, and reoxidise the residue by passing air over it at a red heat. The process has been patented in this country (*Chem. News*, xiv. 154). Mallet (*Bull. Soc. Chim.* [2] vii. 522) passes air for several hours over a mixture of cuprous chloride and kaolin or sand, moistened with 20 p. c. water and heated to 100° in retorts revolving on horizontal axes, and heats the resulting cupric oxychloride more strongly (to about 400°); oxygen is then given off, and the residual cuprous chloride is reoxidised on cooling. If the cupric oxychloride be converted into chloride by evaporating it with 50 p. c. of commercial hydrochloric acid, chlorine is obtained on heating the residue; if a smaller quantity of hydrochloric acid is used, the residue gives off when heated, a mixture of chlorine and oxygen. 100 kilograms of cuprous chloride yield, after conversion into cupric oxychloride, about 3 cubic metres of oxygen, or after conversion into cupric chloride, from 6 to 7 cubic metres of chlorine.

Gondolo (*Compt. rend.* lvi. 488) describes certain modifications of Boussingault's method of preparing oxygen (iv. 298), consisting in adding to the pure baryta a mixture of lime, magnesia, and potassium manganate, to prevent fritting, and heating the mixture in coated cast-iron tubes.

Böttger (*J. pr. Chem.* ciii. 316; cvii. 48) prepares perfectly pure oxygen, free from ozone, by gently heating potassium permanganate, or by decomposing a mixture of the peroxides of lead and barium with very dilute nitric acid (sp. gr. 1.061).

Respecting the estimation of oxygen, see ANALYSIS, ORGANIC (pp. 144, 145).

F. C. Calvert (*Chem. Soc. J.* [2] v. 293) has made observations on the oxidising action of oxygen condensed in the pores of charcoal. Boxwood charcoal lixiviated with hydrochloric acid was dried, ignited, quenched under mercury, then introduced into a measured volume of oxygen, and when the absorption was complete (no carbon dioxide being thereby produced) the oxidisable body was introduced. Hydrogen sulphide and hydrogen phosphide were oxidised in considerable quantity to sulphuric and phosphoric acids, giving rise to a further disappearance of oxygen. Ammonia did not appear to be oxidised to nitric acid. Ethylic and amyllic alcohols were oxidised to the corresponding fatty acids; methylic alcohol less distinctly to formic acid. Ethylene and propylene appeared to yield only carbonic acid and water; amylene, in addition, an ethereal compound which was not isolated.

On oxidation in general, see COMBUSTION. On the oxidation of organic compounds by chromic and permanganic acids, see ANALYSIS, ORGANIC (pp. 149–153).

On the formation of crystallised oxides by electrocapillary diffusion, see E. Becquerel (*Compt. rend.* lxxvii. 1081; *Zeitschr. f. Chem.* [2] v. 131).

OXYHEMOGLOBIN. See BLOOD (p. 352).

OXYHIPPURIC ACID. See HIPPURIC ACID (p. 700).

OXYLEPIDENE. See LEPIDENE (p. 781).

OXYMANDELIC ACID. This name is given by Schultzen a. Riess (*Zeitschr. f. Chem.* [2] vi. 85) to an acid obtained from the urine in a case of acute atrophy of the liver.

OXYMORPHINE. See MORPHINE (p. 841).

OXYPICRIC or STYPNIC ACID. $\text{C}^6\text{H}^3(\text{NO}^2)^3\text{O}^2$.—Stenhouse (*Chem. Soc. J.* [2] iv. 236) prepares this acid by digesting 120 pts. of concentrated aqueous extract of sapan wood for three or four hours with 20 pts. nitric acid of sp. gr. 1.36, evaporating the yellow solution to a syrup, and boiling it for four or five hours with the 8 pts. nitric acid of sp. gr. 1.45. After 3 pts. of acid have been distilled over, the residual liquid is gradually stirred up with 8 pts. of cold water, and the separated oxypticric acid is washed upon a filter. The crude acid, heated to boiling with about 16 pts. water, is then mixed to alkaline reaction with a concentrated solution of potassium carbonate, and the potassium salt, purified by recrystallisation, is decomposed in hot solution by nitric acid.

When a cold solution of calcium hypochlorite is mixed with oxypticric acid, chloropierin is given off, as with picric acid, and on heating the liquid, carbon dioxide is likewise evolved; chloropierin is also formed by treating oxypticric acid with potassium chlorate and hydrochloric acid. The same products, chloropierin and carbon dioxide, are obtained with iodine chloride (Stenhouse).

Ethyl Oxypticrate, $\text{C}^6\text{H}^3(\text{NO}^2)^3\text{O}^2 \cdot \text{C}^2\text{H}^5$, prepared in the same manner as the picrate (g. v.), crystallises from alcohol in nearly colourless laminae, which quickly turn orange-brown on exposure to light. It melts at 120.5° ; volatilises, with partial decomposition, at a higher temperature; is insoluble in water, but soluble in alcohol.

in ether, and especially in benzol. Heated with potash it yields potassium oxypicrate and ethylic alcohol (Stenhouse).

OXYQUINONE. $C^6H^4O^2 = C^6H^4 \begin{Bmatrix} O \\ O \end{Bmatrix}$ O (Malin, *Ann. Ch. Pharm.* cxli. 345).

—A compound produced by fusing rufigallic acid with potash:

On saturating the product with dilute sulphuric acid, agitating the filtered solution with ether, and leaving the ether to evaporate, oxyquinone is obtained in hydrated yellowish crystals containing $C^6H^4O^3 \cdot H^2O$. After being pressed to remove the brown mother-liquor, and recrystallised from boiling water, it forms soft straw-yellow microscopic needles, slightly soluble in cold, easily in boiling water, also in alcohol and ether, having a faint acid reaction, and not volatile. The aqueous solution when heated reduces silver nitrate and alkaline cupric solutions; in the dilute state it colours ferric chloride violet, afterwards blue-green. Oxyquinone, like quinone, has but slight combining tendencies; nevertheless it absorbs dry ammonia gas and forms a yellowish precipitate with lead acetate. It is not converted into quinone by nascent hydrogen.

OXYSULPHOBENZIDE. $C^{12}H^{10}SO^4 = \begin{Bmatrix} C^6H^5SO^2 \\ C^6H^5 \end{Bmatrix} O^2$ (Glutz, *Ann. Ch. Pharm.* cxlvii. 52; *Jahresb.* 1867, p. 635).—Produced by the action of strong sulphuric acid on crystallised phenol. It dissolves easily in boiling water, also in alcohol and ether, and crystallises therefrom in groups of thick needles, fusible at a moderate heat, decomposing at a higher temperature. It unites both with bases and with acids. Its ammoniacal solution deposits short prisms of the salt $C^{12}H^9(NH^4)SO^4$; the sodium salt, $C^{12}H^9NaSO^4$, forms short prisms easily soluble in water and in boiling alcohol. The acetate, $C^{12}H^9(C^2H^3O)^2SO^4$, obtained by heating oxysulphobenzide with excess of acetyl chloride to 130° , crystallises from alcohol in needles, decomposing at the boiling heat into oxysulphobenzide and acetic acid. Nitro-oxysulphobenzide, $C^{12}H^9(NO^2)^2SO^4$, crystallises in scales, and forms with the alkalis and alkaline earths easily soluble deep yellow compounds, e.g. $C^{12}H^9Na^2(NO^2)^2SO^4$ and $C^{12}H^9Ba(NO^2)^2SO^4$. By phosphorus iodide in presence of a little water, it is converted into the compound $C^{12}H^9(NH^4)^2SO^4 \cdot 2HI$, which forms crystals easily soluble in water and in alcohol; caustic soda decomposes it, separating the corresponding base as a white precipitate quickly turning brown on exposure to the air.

OXYVALERIC ACID. $C^5H^9O^3 = C^5H^8(OH) \cdot CO^2H$. *Valerolactic Acid.*—Produced by heating bromovaleric acid with silver oxide and water, and purified by converting it into calcium salt, precipitating the latter with alcohol, converting it into zinc salt, and decomposing this salt with hydrogen sulphide. Crystallises by evaporation over sulphuric acid in large rectangular tables, not deliquescent, but very soluble in water, alcohol, and ether; melts at 80° , and volatilises with vapour of water, also at 100° in the air-bath. The sodium salt, $C^5H^8O^3Na$, the calcium salt, $(C^5H^8O^3)^2Ca + H^2O$, and the zinc salt, $(C^5H^8O^3)^2Zn$, are soluble in water and crystallisable. The copper salt, $(C^5H^8O^3)^2Cu + H^2O$, separates on mixing the calcium salt with cupric acetate, in light green prisms which become anhydrous at 170° . The silver salt, $C^5H^8O^3Ag$, is a bulky precipitate, separating from hot water in feathery crystals (Clark a. Fittig, *Ann. Ch. Pharm.* cxxxix. 199).

OZONE. Soret has determined the density of ozone by comparing its rate of diffusion with that of chlorine. His experiments confirm the result previously obtained by Andrews (iv. 301), that the density of ozone is $1\frac{1}{2}$ times as great as that of ordinary oxygen (*Ann. Ch. Phys.* [4] xiii. 257; *Jahresb.* 1867, p. 123). Another, but less exact method, depending on the absorption of ozone by oil of turpentine, yielded results tending to the same conclusion (*Ann. Ch. Phys.* [4] vii. 113; *Jahresb.* 1865, p. 120).

On the properties of ozone and ozonides, see Schönbein (*J. pr. Chem.* xcv. 469; cii. 145, 155, 164; cv. 226; *Jahresb.* 1865, p. 121; 1867, p. 132; 1868, p. 136). On ozone and so-called antozone, see v. Babo a. Claus (*Ann. Ch. Pharm.* cxl. 348; *Jahresb.* 1866, p. 98); Weltzien (*Ann. Ch. Pharm.* cxxviii. 129; *Jahresb.* 1866, p. 99); C. Hoffmann (*Pogg. Ann.* cxxxii. 607; *Jahresb.* 1867, p. 130).

P. J. Hollmann finds that 1 gram of ozone, in passing to the state of ordinary oxygen, gives off 355·5 units of heat (*Arch. néerland.* iii. 260; *Jahresb.* 1868, p. 136).

According to O. Loew (*Zeitschr. f. Chem.* [2] vi. 65, 269), ozone is produced in active as well as in slow combustion. Air which had passed through the flame of a Bunsen's burner smelt strongly of ozone, turned guaiac paper blue, and quickly separated iodine from potassium iodide.

On the existence of ozone in the air, see ATMOSPHERE (p. 233).

P

PACHNOLITE. A reddish-white quadratic variety of this mineral, of *sp. gr.* 2.74 to 2.76, and the hardness of cryolite, was found by Hagemann (*Sill. Am. J.* [2] xli. 119) to have nearly the composition indicated by the formula $2\frac{1}{2}\text{Ca} \cdot \frac{1}{2}\text{Na}^2\text{F}^2 \cdot \text{Al}^2\text{F}^2 + 2\text{H}^2\text{O}$. On the crystalline form and optical properties of rhombic pachnolite, see Descloizeaux (*ibid.* xliii. 271; *Jahresh.* 1867, p. 1009).

PALICOUREA. *Palicourea Marcgravii*, a Brazilian rubiaceous plant, contains as peculiar principles: 1. A small quantity of an oily narcotic acid substance, myocetic acid, obtained by distilling the acidulated juice.—2. Palicoureic acid, an iron-greening tannic acid, insoluble in water and subliming in needles.—3. Palicourine, a volatile organic base, forming a crystallisable nitrate and sulphate.—4. Several resins (Peckolt, *Arch. Pharm.* cxxvii. 93).

PALLADIUM. On the separation of this metal from Petersburg platinum-residues, see Rössler (*Bull. Soc. Chim.* [2] vi. 233; *Jahresh.* 1866, p. 275).

On the occlusion of hydrogen by palladium, see GASES, ABSORPTION OF (p. 634). According to Wöhler (*Ann. Ch. Pharm.* xli. 144), the quantitative separation of palladium from copper is best effected by precipitating the copper as white sulphocyanate, the solution of palladium chloride being saturated with sulphurous anhydride and the copper precipitated by potassium sulphocyanate. The precipitation of palladium by mercuric cyanide is not exact.

Palladammonium Salts.—The colourless solution of palladammonium chloride in ammonia, which contains tetrammonio-palladious chloride, $4\text{NH}^3 \cdot \text{PdCl}^2$, or ammonio-palladammonium chloride, $\text{N}^2[\text{H}^4(\text{NH}^3)^2\text{Pd}^2]\text{Cl}^2$, gives off ammonia when heated, the liquid on cooling depositing a mixture of the chlorides of palladammonium and ammopalladammonium. If, on the other hand, the palladammonium salt be first moistened with alcohol, and then treated with concentrated ammonia, the mass turns white, and is converted into the ammopalladammonium salt. This latter dissolves when heated, and the solution, evaporated at about 90° , first deposits yellow palladammonium chloride, together with monoclinic prisms of ammopalladammonium chloride, and finally honey-yellow crystals of hydrated palladammonium chloride, $\text{N}^2\text{H}^2\text{PdCl}^2 + \text{H}^2\text{O}$. These crystals are combinations of a quadratic octohedron with a right four-sided prism. They effloresce in contact with the air to opaque pseudomorphs of palladammonium chloride; give off ammonia at 140° ; and leave metallic palladium when more strongly heated. The salt is insoluble in alcohol. The aqueous solution quickly decomposes, especially when heated, depositing ordinary palladammonium chloride. Soda precipitates palladamine without evolution of ammonia. Acids separate the ordinary yellow chloride (Baubigny, *Ann. Ch. Pharm. Suppl.* iv. 253).

PALMITIC ACID. $\text{C}^{16}\text{H}^{32}\text{O}^2$.—By treating sodium palmitate with hypochlorous acid, a chlorinated oil is obtained, probably *dichloropalmitic acid*, which, when treated with alcoholic potash, yields a decomposition-product separating from alcohol in flat nodules (W. Schlebusch, *Ann. Ch. Pharm.* cxlii. 322).

PALMITOLIC ACID. $\text{C}^{16}\text{H}^{32}\text{O}^2$ (Schröder, *Ann. Ch. Pharm.* cxliii. 22).—An acid produced by heating hypogæic dibromide (dibromopalmitic acid), $\text{C}^{16}\text{H}^{30}\text{Br}^2\text{O}^2$, with alcoholic potash to 170° – 180° in a sealed tube for three or four days. The product treated with a little alcohol, filtered, diluted with water, and decomposed with hydrochloric acid, yields palmitolic acid as a crystalline mass, which when pressed and recrystallised from alcohol, forms colourless slender silky needles, melting at 42° , insoluble in water, but easily soluble in alcohol and ether. The acid is monobasic. Its alkali-metal salts are obtained by direct saturation and evaporation. The *potassium* and *sodium* salts are amorphous; the *ammonium* salt forms small indistinct crystals. The *silver* salt, $\text{C}^{16}\text{H}^{32}\text{O}^2\text{Ag}$, is formed, by precipitating an alcoholic solution of the acid with silver nitrate and gradual addition of ammonia, as a white amorphous powder easily blackened by light. The *barium* salt is obtained in like manner, by precipitation with a concentrated solution of barium acetate in dilute alcohol, as a white precipitate, which dissolves only in boiling alcohol, and separates in the granulo-crystalline form on cooling. The *copper* salt is a blue-green precipitate.

Palmitolic acid unites with 1 mol. bromine, forming the dibromide, $C^{16}H^{32}Br^{2}O_2$ (dibromo-hypogæic acid); with excess of bromine in sunshine (with partial decomposition and evolution of hydrobromic acid) it forms the tetrabromide, $C^{16}H^{32}Br^{4}O_2$ (tetrabromopalmitic acid), which crystallises from alcohol in light yellow laminae.

Monobromopalmitolic acid, $C^{16}H^{31}BrO_2$, is produced by the action of boiling alcoholic potash on monobromo-hypogæic dibromide (p. 727) according to the equation:

It has been obtained only in an impure state, as a solid dark brown mass melting at 31° , heavier than water, soluble in alcohol and ether.

PALMITOXYLIC ACID, $C^{16}H^{32}O_4$, is produced, together with suberic acid and suberic aldehyde, by gradually adding fuming nitric acid to palmitolic acid, assisting the action at first by a gentle heat:

The suberic acid is dissolved out of the product by repeated boiling with water; the washed residue is dissolved in hot alcohol; and the lower dark-coloured oily layer of the filtrate, consisting chiefly of suberic aldehyde, is separated after cooling from the supernatant yellow solution of palmitoxylic acid. The crystalline mass which remains on evaporating this solution, when pressed between filtering-paper and recrystallised from hot absolute alcohol, yields pure palmitoxylic acid in iridescent yellowish laminae, melting at 64° , insoluble in water, easily soluble in alcohol and ether. It is monobasic. The silver salt, $C^{16}H^{31}O_4Ag$, obtained from the sodium salt by precipitation, is white, nearly insoluble in water, turns dark violet when exposed to light, and may be heated to 150° without decomposition.

PANATOMS. G. Hinrichs has endeavoured to reduce the chemistry of the present day to a system of atomic mechanics, starting from the hypothesis that all the elements are formed of a single primary substance, pantogen, the atoms of which are regarded as material points, and as equal to one another. For the development of the system we must refer to the original treatise: *Atommechanik, oder die Chemie eine Mechanik der Panatome*, 4to, Iowa, 1867. A short abstract of it is given in the *Jahresbericht für Chemie*, 1867, p. 20.

PAPAVERINE. This base has been re-examined by Hesse (*Ann. Ch. Pharm.* cliii. 75), who prepares it from the precipitate P, obtained from aqueous opium extract, as described under OPIUM-NASES (p. 883). This precipitate digested with excess of oxalic acid yields crystalline oxalate of papaverine. It is better, however, first to dissolve the precipitate in acetic acid, remove thebaine by means of tartaric acid, precipitate the mother-liquor of the tartrate with ammonia, and treat the resinous precipitate with a small quantity of alcohol, whereby it is gradually converted into crystals, while an amorphous base passes into the solution. The crystals are dissolved in excess of oxalic acid, and the oxalate is purified by repeated crystallisation from boiling water, till it dissolves without colour in strong sulphuric acid. The oxalic acid is then removed by calcium chloride, and the base is precipitated by ammonia, and obtained pure by recrystallisation from hot alcohol.

Papaverine forms delicate colourless prisms, tasteless, without action on litmus, melting at 147° , turning reddish, and finally decomposing at a higher temperature. According to Merck (iv. 338), it assumes a deep blue colour when strong sulphuric acid is poured upon it. According to Hesse, on the other hand, pure papaverine dissolves without colour in strong sulphuric acid at ordinary temperatures, but the solution when heated becomes dark violet, like a similar solution of codamine or laudanine (pp. 480, 774). Papaverine which had not been completely purified by oxalic acid dissolved in strong sulphuric acid with very dark colour. Papaverine dissolves in acetic acid, but does not neutralise it; dilute sulphuric, nitric, or hydrochloric acid added to this solution, produces a milky turbidity and ultimate precipitation of the sulphate, nitrate, or hydrochloride of papaverine; the chlorides of sodium and calcium act in like manner, precipitating papaverine as hydrochloride; sodium nitrate precipitates the nitrate. With a solution of the acetate of a certain degree of dilution, the hydrochloride and nitrate are obtained in fine crystals. Potash and soda produce in the acetate solution a resinous precipitate, which soon becomes crystalline, and is insoluble in excess of the reagent.

Papaverine contains, according to the mean of Hesse's analysis, 71.77 p. c. carbon, 6.02 hydrogen, and 4.26 nitrogen, agreeing with the formula $C^{27}H^{21}NO^4$ (71.76 C, 5.98 H, and 3.99 N). Former analyses by Merck and Anderson (iv. 338) gave a

smaller proportion of carbon (70.47–70.71 p. c.), leading to the formula $C^{10}H^{10}NO_4$. Hesse's analysis of several of the salts of papaverine gave results in accordance with his formula of the base. These salts dissolve in strong sulphuric acid without coloration.

The name *papaverine* has also been applied by Deschamps d'Arallon (*Ann. Ch. Phys.* [4] i. 453) to another base (better called pseudopapaverine), extracted from the dried capsules of *Papaver somniferum*. It is described as colourless, inodorous, bitter, acid to test-paper; more soluble in hot water than in cold; insoluble in ether and in chloroform; crystallising from alcohol in short nacreous needles; precipitated from solution in hydrochloric acid by mercuric chloride. A solution of iodine in potassium iodide colours it in aqueous solution blue, and forms a brown precipitate with the solution in hydrochloric acid.

PAPAVEROSINE. A substance obtained from the same dried poppy capsules, after exhaustion with water, by digesting them with alcohol of 56 p. c., treating the alcoholic extract with ether, dissolving the ethereal extract in hydrochloric acid, and repeatedly crystallising the base precipitated by magnesia from alcohol. It is colourless, inodorous, nearly tasteless, slightly alkaline; soluble in alcohol, ether, chloroform, hot olive oil, and benzol; does not crystallise from ether or chloroform, but separates from the other solvents in prisms apparently monoclinic. Strong sulphuric acid colours it violet, changing to red when heated, and to dark orange on addition of a little nitric acid. Its solution gives a whitish precipitate with platinic chloride; yellow with potassium chromate and with solution of iodine in potassium iodide; white with potassio-mercuric iodide, ammonium molybdate, barium peroxide, potassium ferrocyanide and ferricyanide (Deschamps, *loc. cit.*).

PARA. Respecting the meaning of this prefix in the AROMATIC SERIES, see page 798.

PARABANIC ACID, $C^4H^2N^2O^2$, is obtained in crystals by heating uric acid with manganese dioxide and water, and gradually adding sulphuric acid as long as any action takes place (Wheeler, *Bull. Soc. Chim.* [2] vii. 521); also by heating uric acid with potassium or sodium nitrite, adding sulphuric acid, and evaporating over the water-bath (Gibbs, *Deut. chem. Ges. Ber.* 1867, p. 341). Parabanic acid heated with potassium permanganate in presence of sulphuric acid is ultimately converted into carbon dioxide and ammonia: $C^4H^2N^2O^2 + 2H^2O + O = 3CO^2 + 2NH^3$ (Gibbs).

PARACONIC ACID. An acid isomeric with itaconic acid, produced by heating itamono-chloropyrotartaric acid with water. (See ITACONIC ACID, p. 760.)

PARACOUMARIC ACID. $C^9H^9O^3$ (Hlasiwetz, *Ann. Ch. Pharm.* cxxxvi. 31).—This acid, isomeric with coumaric acid (p. 498), is extracted by ether from aloes previously exhausted with water containing sulphuric acid. After repeated crystallisation from weak spirit, with addition of animal charcoal, it forms sickle-shaped or fureate needles, slightly soluble in cold, more freely in boiling water, most easily in warm alcohol or ether. It is nearly tasteless, has a strong acid reaction; melts at 179° – 180° ; produces a dark golden-brown coloration with ferric chloride in alcoholic solution; does not reduce either silver nitrate or an alkaline cupric solution. It is monobasic and forms crystalline salts. $C^9H^9O^3(NH^4) + H^2O$ crystallises in monoclinic tables; $(C^9H^9O^3)^2Cd + 3H^2O$ in stellate groups of needles; $(C^9H^9O^3)^2Cu + 6H^2O$ in sparingly soluble greenish-blue needles; $C^9H^9O^3Ag$ is a white bulky precipitate.

Paracoumaric acid is converted by sodium-amalgam into hydroparacoumaric acid (p. 716), and by nitric acid, or by fusion with potash, into paraoxybenzoic acid, just as coumaric acid is converted into salicylic acid (p. 498).

PARADATISCETIN. $C^{15}H^{10}O^8$.—A compound isomeric with datiscetin (ii. 306) and luteolin, produced by fusing quercetin with potash, and separated, on supersaturating the fused mass with hydrochloric acid, as a flocculent substance, which crystallises from very weak spirit in yellowish needles. It dissolves easily and with acid reaction in dilute alcohol, less easily in ether, and is nearly insoluble in water; the alcoholic solution is coloured violet by ferric chloride, yellow by potash, turning green in contact with the air, red or red-brown by aqueous chlorine or bromine. Silver nitrate and alkaline cupric solution are reduced when heated with it. Boiled with the carbonates of alkaline earths, it yields hydrated salts, which crystallise in long needles; the barium salt dried at 100° is $(C^{15}H^9O^8)^2Ba + 2H^2O$; the strontium salt, $(C^{15}H^9O^8)^2Sr + 2H^2O$. Paradatiscetin fused with potash yields phloroglucin, but neither quercetic nor protocatechuic acid (Hlasiwetz a. Pfandler, *J. pr. Chem.* xxi. 65; *Jahresb.* 1864, p. 563).

PARAFFINE. See HYDROCARBONS (p. 705).

PARALBUMIN. See PROTEIDS.

PARAMYLENE. See AMYLENES, POLYMERIC (p. 122).

PARAOXYBENZAMIDE. $C^6H^4(OH).CONH^2$.—See OXYBENZAMIDE (p. 889).

PARAOXYBENZOIC ACID. $C^6H^4O^3 = C^6H^4(OH).CO^2H$.—This acid, originally obtained by the action of hydriodic acid on anisic or methyl-para-oxybenzoic acid (iv. 352), is more easily prepared by heating 1 pt. of anisic acid with 3 or 4 pts. of potassium hydrate and a little water, till the mixture fuses without frothing, then acidulating with sulphuric acid, agitating with ether, and leaving the ethereal solution to evaporate (Barth, *Wien. Akad. Ber.* liv. [2] 633). It is also produced by the following reactions:

1. By fusing benzoïn or acaroïd resin with potassium hydrate. The resin is heated in a silver basin with three times its weight of potash and a small quantity of water; the mass when tranquilly fused is dissolved in water (4 pts. to 1 pt. potash); and the mixture is strongly acidulated with sulphuric acid. The liquid filtered from unaltered resin is then agitated with three times its volume of ether; the ethereal extracts are distilled; and the residue mixed with a little water is evaporated over the water-bath. It then gradually deposits para-oxybenzoic acid, while, in the case of benzoïn, the mother-liquor retains pyrocatechin, a compound of paraoxybenzoic acid with protocatechuic acid, and a substance which crystallises from alcohol and turns ferric chloride red. Acaroïd resin yields by the same treatment a large proportion of paraoxybenzoic acid (36 grms. from 9 ounces), the ethereal mother-liquor retaining pyrocatechin, resorcin, and the compound of paraoxybenzoic and protocatechuic acid just mentioned (Hlasiwetz a. Barth, *Ann. Ch. Pharm.* cxxxiv. 265; cxxxviii. 61).—2. By fusing tyrosine with potassium hydrate (Barth, *ibid.* cxxxvi. 110):

3. By fusing carthamin with potassium hydrate (Malin, *ibid.* cxxxvi. 115):

Basic barium paraoxybenzoate, $C^6H^4O^3Ba$, is easily prepared (like the corresponding salicylate) by saturating the acid with barium carbonate, and mixing the solution with baryta-water; it then separates as a sandy crystalline powder, nearly insoluble in cold water. A corresponding *calcium salt* (mixed however with acid salt) is obtained by saturating the acid with a solution of lime in sugar-water (Barth).

Paraoxybenzoic Ethers (Graebe, *Ann. Ch. Pharm.* cxxxix. 134. Ladenburg, *ibid.* cxli. 241. Ladenburg a. Fitz, *ibid.* 247. Barth, *J. pr. Chem.* c. 366).—Paraoxybenzoic acid, like its isomerides, oxybenzoic and salicylic acids, is diatomic and monobasic, and can therefore form three kinds of ethers, as illustrated by the following formulæ:

Methylic Paraoxybenzoate is formed by heating paraoxybenzoic acid, methyl-iodide, and potash in equivalent proportions to 120° in a sealed tube:

On treating the product with water, separating the insoluble portion by filtration, drying it in the air, and distilling, nearly the whole of the methylic ether passes over at 280° , and immediately solidifies. When purified by recrystallisation from ether, it is quite insoluble in cold water, slightly soluble in boiling water, and separates on cooling as a crystalline oil. It dissolves easily in alcohol and ether, and crystallises from the latter in large tables. Melts at 17° and distils at 283° . Heated with strong ammonia to 100° it forms paraoxybenzamide (p. 899) (Ladenburg a. Fitz).

Methylic paraoxybenzoate is isomeric with several other compounds, as shown by the following formulæ:

Methylic Paraoxybenzoate.

Methyl-paraoxybenzoic acid.

Formobenzoic acid.

Phenoxacetic acid.

Cresotic acid.

Dimethylic Paraoxybenzoate, Methylic Methylparaoxybenzoate, or Methyl Anisate, $\text{C}^6\text{H}^4(\text{OCH}^3) \cdot \text{CO}^2\text{CH}^3$, is formed by heating 2 mol. potassium hydrate with 1 mol. paraoxybenzoic acid and 2 mol. methyl iodide:

When separated with water and distilled, it forms a white crystalline mass, melting at 45° , boiling at 255° , and identical with the ethyl anisate prepared by Cahours (i. 301). By boiling with potash it is converted into methyl-paraoxybenzoic or anisic acid. The second atom of methyl cannot be removed by heating with aqueous or alcoholic potash or by hydriodic acid, the product in either case being, not paraoxybenzoic, but anisic acid (Ladenburg a. Fitz).

Ethylic Paraoxybenzoate, $\text{C}^6\text{H}^5\text{O}^2 \cdot \text{C}^2\text{H}^5$, prepared by treating the alcoholic solution of the acid with hydrochloric acid gas, precipitating with water, drying over sulphuric acid, and distilling, is crystalline, melts at 112.5° , boils at 297° – 298° , and is converted by treatment with soda-ley, or by adding sodium to its ethereal solution, into solid ethylic sodioparaoxybenzoate, $\text{C}^6\text{H}^4(\text{ONa}) \cdot \text{CO}^2\text{C}^2\text{H}^5$. This latter compound is reconverted by hydrochloric acid into ethylic paraoxybenzoate; and by boiling its aqueous solution, it is resolved into alcohol and sodium paraoxybenzoate. Its alcoholic solution heated for some hours to 110° – 120° with methyl iodide yields ethylic anisate (Graebe):

Diethylic Paraoxybenzoate, $\text{C}^6\text{H}^4(\text{C}^2\text{H}^5)^2\text{O}^2 = \text{C}^6\text{H}^4 \cdot \begin{Bmatrix} \text{OC}^2\text{H}^5 \\ \text{CO}^2\text{C}^2\text{H}^5 \end{Bmatrix}$, is prepared, like the corresponding methyl-compound, by heating 1 mol. paraoxybenzoic acid, 2 mol. ethyl iodide, and 2 mol. potassium hydrate to 120° , and may be separated by water. It is a colourless oil having a faint but agreeable odour, heavier than water, insoluble therein, but easily soluble in alcohol and ether; distils between 273° and 276° (Ladenburg a. Fitz).

Ethyl-paraoxybenzoic Acid, $\text{C}^6\text{H}^5 \cdot \begin{Bmatrix} \text{OC}^2\text{H}^5 \\ \text{CO}^2\text{H} \end{Bmatrix}$, homologous with anisic acid, is easily produced by boiling the last-described ether with potash. It is still less soluble in water than anisic acid; crystallises from boiling water in needles resembling the latter; sublimes without decomposition, and melts at 195° . Its sodium salt is moderately soluble in cold water, and separates in well-defined crystals very much like the anisate. The silver salt, $\text{C}^6\text{H}^4(\text{OC}^2\text{H}^5) \cdot \text{CO}^2\text{Ag}$, is nearly insoluble in boiling water, and crystallises therefrom in long needles. The calcium salt is a white crystalline precipitate, which separates from hot water in flat needles; it becomes anhydrous at 150° , and then consists of $(\text{C}^6\text{H}^5\text{O}^2)^2\text{Ca}$. The barium salt, $(\text{C}^6\text{H}^5\text{O}^2)^2\text{Ba}$, (at 100°) resembles the calcium salt and crystallises from water in laminæ; the lead salt exhibits similar characters (Ladenburg a. Fitz).

Ethyl-paraoxybenzoic acid is isomeric, not only with ethylic paraoxybenzoate, ethyl-salicylic acid, ethylic salicylate, ethylic and dimethylic oxybenzoate, but likewise with phloretic acid, cresoxacetic acid, and the acid which Cannizzaro obtained by the action of potash on anisic cyanide, probably methyl-paraoxyalphanolonic acid, $\text{C}^6\text{H}^4(\text{OCH}^3) \cdot \text{CH}^2\text{CO}^2\text{H}$.

An acid of the same composition is produced by passing carbon dioxide into a solution of sodium in ethyl-phenol. (See PHENOLIC ETHERS.) The acid thus prepared from solid ethyl-phenol melts at 118° – 120° ; that from liquid ethyl-phenol at 115° – 117° . Both are coloured violet by ferric chloride, and yield a soluble barium salt, the acid of which melts at 115° – 117° . The very great difference of melting point between this acid and the ethyl-paraoxybenzoic acid obtained by Ladenburg a. Fitz, shows that the two are isomeric, not identical; the acid prepared from ethyl-phenol is perhaps ethyl-metaparaoxybenzoic acid. This acid is converted by highly concentrated nitric acid into ethyl dinitrophenol, $\text{C}^6\text{H}^3(\text{NO}^2)^2 \cdot \text{OC}^2\text{H}^5$ (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] v. 461; *Chem. Centr.* 1870, 46).

Chloro-paraoxybenzoic acid, $\text{C}^6\text{H}^4\text{ClO}^2 = \text{C}^6\text{H}^4\text{Cl} \cdot \begin{Bmatrix} \text{OH} \\ \text{CO}^2\text{H} \end{Bmatrix}$ is prepared by the action of chlorine on silver paraoxybenzoate, extraction with ether, and recrystallisation from hot water with addition of animal charcoal. Hot-saturated solutions solidify on cooling to a stiff, dazzling white, crystalline pulp; weaker solutions deposit

concentric or arborescent groups of silky crystals. The acid dissolves easily in alcohol and ether, and in 272.5 pts. of cold water, melts at 187.5° to 188° , and sublimes in small transparent needles. Neutral or slightly acid solutions form a red-brown precipitate with ferric chloride (R. Peltzer, *Ann. Ch. Pharm.* cxlvi. 284; *Zeitschr. f. Chem.* [2] v. 225).

Dibromo-paraoxybenzoic Acid. $C^7H^4Br^2O^3$.—The ethylic ether of this acid separates on adding saturated bromine-water to an alcohol solution of ethylic paraoxybenzoate diluted with hot water, in white flocks which separate from alcohol in short shining needles (Barth, *J. pr. Chem.* c. 366).

Iodoparaoxybenzoic acids are produced by the simultaneous action of iodine and iodic acid on paraoxybenzoic acid; the best proportions are those indicated by the following equation:

The paraoxybenzoic acid is dissolved in hot water in a flask provided with an upright condenser; iodine and iodic acid are added in powder; and the liquid is heated nearly to boiling for about five minutes, and then quickly filtered. Di-iodoparaoxybenzoic acid then remains on the filter, while the mono-iodated acid, contaminated with a small quantity of paraoxybenzoic acid separates from the filtrate. The mono-iodated acid is purified by repeated crystallisation from hot water, with addition of animal charcoal: it first separates in granules, but when nearly pure, in small needles having a glassy lustre (Peltzer, *loc. cit.*). It is also produced, though not in the pure state, by heating paraoxybenzoic acid with potassium iodate and sulphuric acid: the product is a resinous mass which when fused with potash is resolved into potassium iodide and protocatechuic acid (Barth; Peltzer).

Monoiodoparaoxybenzoic acid, in the air-dried state, contains $2C^7H^4IO^3 + H^2O$, and gives off its water at 100° . It dissolves in 576 pts. of cold water, much more easily in hot water, very easily in alcohol and ether. It melts at 160° , decomposes at 192° (iodosalicic acid does not melt below 196°); when very gradually heated it sublimes, much below its melting point, in silky needles two lines long. The aqueous solution forms a dingy brown precipitate with ferric chloride. The *monosodic salt*, $C^7H^3I(OH).CO^2Na$, formed by adding the acid to a hot solution of sodium carbonate in sufficient quantity to produce strong acid reaction, removing the excess of acid by ether, and strongly concentrating the remaining solution, crystallises in fine efflorescent monoclinic crystals, often concentrically grouped. The *disodic salt*, $C^7H^2I(ONa).CO^2Na + 5H^2O$, is obtained by adding the acid to excess of hot aqueous sodium carbonate, adding a large quantity of alcohol, and evaporating the filtered solution to dryness. On redissolving in absolute alcohol and evaporating in a vacuum, the salt is obtained in hygroscopic silky needles, having a neutral reaction, and giving off their water at 130° . The *barium salt*, $(C^7H^4IO^3)_2Ba + 7H^2O$, forms transparent rhombic tables having their prismatic edges truncated; becomes anhydrous at 100° . The use of an excess of barium carbonate does not give rise to a salt richer in barium. The *silver salt*, $C^7H^4IO^3Ag$, is a white pulverulent precipitate nearly insoluble in water, easily soluble in ammonia (Peltzer).

Di-iodoparaoxybenzoic acid, $C^7H^2I^2O^3 = C^7H^2I^2(OH).CO^2H$, is easily purified by boiling it several times with water, dissolving the residue in sodium carbonate, precipitating with hydrochloric acid, then dissolving in strong alcohol, decolorising with animal charcoal, and mixing the solution with a sufficient quantity of water to produce turbidity; the acid is then deposited on cooling in small colourless needles. It is nearly insoluble in boiling water; dissolves easily in alcohol and ether; decomposes when heated, without previous fusion; and cannot be sublimed. Its two *sodium salts* are prepared similarly to those of the mono-iodated acid. The salt $C^7H^2I^2ONa + 7H^2O$ forms tufts of delicate, iridescent, efflorescent needles. The *disodic salt*, $C^7H^2I^2ONa^2 + 6H^2O$, forms transparent rhombic tables: both are easily soluble in water. From these salts two corresponding *silver salts* are obtained as flocculent curdy precipitates detonating when heated. The *barium salt*, $C^7H^2I^2O^3Ba$, is separated by alcohol from its aqueous solution, as a gelatinous precipitate, which dries up to a very loose white powder. The *calcium salt*, $C^7H^2I^2O^3Ca + 2H^2O$, crystallises from concentrated solution in nacreous laminae, easily soluble in cold water. The *lead salt*, $C^7H^2I^2O^3Pb$, is formed, as a bulky precipitate, with elimination of acetic acid, when a solution of the disodic salt is mixed with lead acetate; when heated it swells up like mercuric sulphocyanate. Both mono- and di-iodoparaoxybenzoic acid are easily reduced by sodium-amalgam to para-oxybenzoic acid. The di-iodated acid is but imperfectly decomposed by fusion with sodium carbonate, even at 200° ; the fused mass assumes a flesh-red colour on exposure to the air (Peltzer).

Iodo-methylparaoxybenzoic or *Iodanisic acid*, $C^6H^4IO^3 = C^6H^4 \begin{cases} OCH^3 \\ CO^2H \end{cases}$, is produced by heating 4 grms. of anisic acid to 145° – 150° with the quantities of iodine and iodic acid corresponding to the equation :

The crystallised portion of the product contains, besides anisic acid, which may be extracted by boiling water, iodanisic acid and a non-acid body. The iodanisic acid is extracted by hot solution of sodium carbonate; the exactly neutralised solution precipitated by barium chloride; and the barium salt recrystallised from boiling water till the acid separated from it melts at 234.5° . The acid is nearly insoluble in boiling water, dissolves in 165 pts. of ether at ordinary temperatures, somewhat more easily in boiling ether and in alcohol, and crystallises from the two latter in needles having a vitreous lustre. Its ammonium salt crystallises in nodular groups of small needles; the sodium salt, $C^6H^4IO^3Na + 2H^2O$, in concentrically grouped needles; the barium salt, $(C^6H^4IO^3)^2Ba + 3H^2O$, in vitreous prisms; the calcium salt, $(C^6H^4IO^3)^2Ca + 3H^2O$, in nacreous laminae. The lead salt, $(C^6H^4IO^3)^2Pb$, (at 100°) is a curdy precipitate, which cakes together on boiling. The silver salt, $C^6H^4IO^3Ag$, separates from boiling water in microcrystalline laminae quickly blackened by light. The copper and iron salts are brown precipitates insoluble in water (Peltz).

Nitroparaoxybenzoic and Amidoparaoxybenzoic Acids (Barth, *loc. cit.*).—The *dinitro-acid*, $C^6H^3(NO^2)^2O^3$, is obtained (but not quite free from the following compound) by dissolving paraoxybenzoic acid in warm nitric acid of sp. gr. 1.40, and crystallises from water in stellate groups of yellowish needles, which acquire a lemon-yellow colour on exposure to light and air. The *mononitro-acid*, $C^6H^4(NO^2)O^3$, which is more easily obtained pure, separates from a solution of paraoxybenzoic acid in 1 vol. nitric acid of 1.40 and 6 vol. water, in flesh coloured crystals, which, after recrystallisation, exhibit sickle-shaped forms under the microscope. Both these nitro-acids, when treated with tin and hydrochloric acid, quickly yield double compounds of the hydrochlorides of the corresponding amido-acids with stannous chloride.

Ethylie Dinitroparaoxybenzoate is formed by dissolving ethylic paraoxybenzoate in strong nitric acid, and separates on cooling in radiate feathery crystals, and on addition of water as an oil which quickly crystallises in warty masses; after recrystallisation from alcohol it forms nearly colourless, very light needles, which become strongly electric by friction. *Ethylie mononitroparaoxybenzoate*, $C^6H^3(NO^2)O^3.C^2H^5$, is prepared by heating the paraoxybenzoic ether with 1 vol. nitric acid of sp. gr. 1.40 and 6 vol. water, till an oil separates which crystallises on cooling. Both these nitrated ethers melt below 100° , and solidify in the crystalline state on cooling.

The mononitrated ether reduced with tin and hydrochloric acid yields a yellow solution, which when freed from tin by hydrogen sulphide, deposits colourless laminae of the *hydrochloride of ethyl amidoparaoxybenzoate*, $C^6H^3(NH^2)O^3(C^2H^5).HCl + \frac{1}{2}H^2O$. This compound in very dilute solution is coloured blood-red by ferric chloride, and is therefore only isomeric with tyrosine hydrochloride, which does not exhibit this reaction. (See TYROSINE.) *Ethyl amidoparaoxybenzoate* cannot be separated from this compound, on account of its instability. The mother-liquor of the hydrochloride, especially if mixed with hydrochloric acid, deposits crystals of the *hydrochloride of amidoparaoxybenzoic acid*. This last-mentioned compound mixed in moderately dilute solution with sulphuric acid, solidifies to a crystalline pulp consisting of the *sulphate of amidoparaoxybenzoic acid*, which when treated with cold concentrated nitric acid, acquires a splendid dark cherry-red colour. *Amidoparaoxybenzoic acid*, $C^6H^3(NH^2)O^3 + \frac{1}{2}H^2O$, prepared by decomposing the sulphate with baryta-water, neutralising the filtrate with lead carbonate, and decomposing the resulting lead salt with hydrogen sulphide, crystallises in needles, which decompose even below 100° , and appear under the microscope as hexagonal scalenohedrons, often with curved faces (Barth).

PARATOLUIDINE. See TOLUIDINE.

PARTZITE. A silver ore discovered by A. W. Partz in the Blind Spring mountains, Mono County, California. It forms dull amorphous masses having a conchoidal to uneven fracture, and yellowish-green, blackish-green, or black colour. Hardness between 3 and 4. Sp. gr. = 3.8. Contains 47.65 p. c. Sb^2O^3 , 32.11 CuO, 6.12 Ag^2O , 2.01 PbO, 2.33 FeO, and 8.29 water (= 98.51), agreeing with the formula $(CaO) : Ag^2O : PbO : FeO : Sb^2O^3 + 3H^2O$ (Arents, *Sill. Am. J.* [2] xliii. 362).

PASTREITE. A yellow amorphous ferric sulphate, found, together with cerusite and fibroferrite, at Paillières, near Alais, in the Dép. du Gard, on the

rubbish-heaps of mines from which argentiferous galena and iron pyrites are obtained. Contains 30.47 p. c. SO_2 , 46.50 Fe^{2+}O^3 , and 16.04 water, together with 1.86 As_2O^3 , 2.40 SiO_2 , 1.25 PbO , and 0.89 lime, clay, and manganese (Bergemann, *Jahresb.* 1867, p. 1005).

PATELLARIC ACID. $\text{C}^7\text{H}^{20}\text{O}^{10}$.—This acid, obtained some time ago by Knop, from the lichen *Parmelia scruposa* or *Patellaria scruposa*, has been further examined by Weigelt (*Zeitschr. f. Chem.* [2] v. 298). It does not appear to be identical with any of the known lichen acids. It unites easily with bases, and yields with cold baryta-water a salt having a transient blue colour. Boiling baryta-water decomposes it, forming carbonate and oxalate of barium, together with a barium salt of a new acid (β patellaric acid) possessing, to a certain extent, essentially different qualities. Patellaric acid forms two series of salts, in which 1 and 2 at. H are replaced by metals. The formation of the salt $\text{C}^7\text{H}^{18}(\text{NH}^4)\text{O}^{10}$ appears to require the aid of sunshine. Among the decomposition-products of the acid are carbonic acid, oxalic acid, and orcin. The lichen contains between 2 and 3 per cent. of patellaric acid. The acid is situated between the layers of the outer bark and the gonidia, where it was detected microscopically by the reaction with baryta-water.

PATSCHOULI. Volatile oil of patschouli gradually deposits a camphor or stearoptene, the formation of which may be accelerated by dehydrating the oil with calcium chloride. This camphor is homologous with that of Borneo, and has the composition $\text{C}^{15}\text{H}^{28}\text{O}$; vapour density obs. = 8.00; calc. = 7.85. It melts at 54° – 55° , boils at 296° , and has a sp. gr. of 1.051 at 4.5° . It is insoluble in water, easily soluble in alcohol and ether, and separates from these solutions by slow evaporation, sometimes in large and very well-defined hexagonal prisms terminated by six-sided pyramids. The alcoholic solution is levogyrate, a solution of 1 grm. in 5.3 c. c. alcohol in a tube 0.05 met. long producing a deflection of 9.1° . The camphor distilled over zinc chloride yields a hydrocarbon, $\text{C}^{15}\text{H}^{28}$, which boils at 248° – 252° , and appears to be converted into polymeric hydrocarbons at slightly higher temperatures. The oil from which the camphor has been deposited passes over almost entirely between 282° and 294° , has the same composition as the camphor, and yields the same hydrocarbon when treated with zinc chloride. It is also levogyrate, but less so than the camphor, producing under the conditions above mentioned, a deflection of only 3° (H. Gal, *Compt. rend.* lxxiii. 406).

PECTOLITE. The mineral from Niederkirchen, near Wolfstein in the Rhein-pfalz, called *oeselite* by Breithaupt, appears, from a renewed examination by v. Kobell (*J. pr. Chem.* xvii. 493; *Jahresb.* 1866, p. 935), to have the composition and all the properties of pectolite. It is intergrown with a brown friable mineral, very similar to it in structure, which appears to have been formed from it by the action of water and carbonic acid.

PECTOUS SUBSTANCES (iv. 563). On the preparation of pectin from turnips, see Stüde (*Ann. Ch. Pharm.* cxxxi. 244; *Jahresb.* 1864, p. 587).*

On the preparation of metapectic acid from horse-chestnut bark, see Rochleder (*Zeitschr. f. Chem.* [2] iv. 381). Metapectic acid heated with excess of potassium hydrate is resolved into formic and protocatechuic acids:

The formation of pyropectic acid, $\text{C}^7\text{H}^{18}\text{O}^8$, from metapectic acid, by the action of heat, is represented by the equation: $2\text{C}^8\text{H}^{10}\text{O}^7 = \text{C}^7\text{H}^{18}\text{O}^8 + 2\text{CO}_2 + \text{H}_2\text{O}$ (Rochleder).

Scheibler (*Deut. chem. Ges. Ber.* 1868, pp. 58. 108; *Zeitschr. f. Chem.* iv. 433) prepares metapectic acid by heating turnip pulp with milk of lime on the water-bath, decomposing the resulting calcium salt with ammonium carbonate, precipitating the ammoniacal solution with basic lead acetate, separating the acid by hydrogen sulphide (removing the last portions of lead, if necessary, by sulphuric acid), and decolorising it with animal charcoal free from lime. The acid thus prepared possesses all the properties of that described by Frémy (iv. 369), excepting that its alkali-metal salts are not precipitated by basic or neutral lead acetate in neutral solution, but only on addition of ammonia; and that, instead of being optically inactive, it exhibits a very strong levogyration, 1 pt. of it being sufficient to neutralise the dextrogyrate power of 1½ pt. dextroglucose. This levogyrate power is not altered by saturating or supersaturating the solution of the acid with alkalis or alkaline earths; but on boiling the solution with a strong acid, mineral or organic, it quickly diminishes,

* See also vol. iv. p. 364, in which (line 9 from bottom) read 'turnips' instead of 'radishes.'

becomes nothing, and then passes into dextrogyration, ultimately equal in magnitude to the original levogyration. This change arises from the resolution of the metapæctic acid into an organic acid precipitable by lead acetate, and a dextrogyrate sugar, pectin-sugar: metapæctic acid is therefore a glucoside.

Pectin-sugar, $C^6H^{10}O^6$, crystallises in long brittle prisms with dihedral summits. It is less sweet than cane-sugar, dissolves easily in boiling water, and separates therefrom on cooling. At 160° it melts to a transparent liquid, which solidifies to a crystalline mass on cooling; at higher temperatures it carbonises, and gives off an acid distillate. It is carbonised by sulphuric acid, and when treated with nitric acid yields oxalic but no mucic acid. Alkalis and alkaline earths are dissolved by it, and quickly turn it brown when heated with it; the lime-solution is precipitated by alcohol. Its dextrogyrate power exceeds that of all other kinds of sugar except trehalose and lactose, and is 1.6 time as great as that of dextroglucose; $[\alpha] = +118^\circ$ for the transition tint. Pectin-sugar very easily reduces an alkaline solution of potassio-cupric tartrate (Fehling's solution). From an ammoniacal silver solution at 100° it throws down a speculum of silver. It is not brought into alcoholic fermentation by yeast (Scheibler).

PELARGONIC ACID. $C^9H^{18}O^2$.—The compound of this acid with nitrogen dioxide, $C^9H^{18}O^2.N^2O$, which Chiozza obtained as a secondary product in the preparation of pelargonic acid by the action of nitric acid on oil of rue (*Compt. rend.* xxxv. 797; *Jahresb.* 1852, p. 499), may be prepared, according to Alexeyeff (*Zeitschr. f. Chem.* [2] i. 736), by heating oil of rue with an equal volume of nitric acid of sp. gr. 1.2. When the action is complete, the oil which separates is washed with water and treated with potash. The liquid diluted with water deposits an abundant precipitate of the potassium salt of nitroso-pelargonic acid, which may be purified by recrystallisation from boiling water. The barium salt obtained by double decomposition has, according to Chiozza, the composition $(C^9H^{18}O^2.N^2O)^2Ba$. The silver salt of analogous constitution burns with a greenish flame. The acid separated from its potassium salt is an oily liquid, which when heated suddenly gives off large quantities of nitrogen dioxide mixed with combustible gases (Chiozza).

PELARGONITRILE. $C^9H^{17}N$, or **OCTYL CYANIDE**, $C^8H^{17}.CN$.—See CYANIDES, ALCOHOLIC (p. 525).

PENNINE. Fellenberg (*Jahresb.* 1867, p. 992) found for pennine: A from Rimpfischgrat, B from Zermatt, the following percentage composition, whence he deduces for A the formula $5(4MgO.3SiO^2) + 2(3MgO.Al^2O^3) + 20H^2O$; for B the formula $3(4MgO.3SiO^2) + 2(2MgO.Al^2O^3) + 12H^2O$:

SiO ²	Al ² O ³	Cr ² O ³	Fe ² O ³	FeO	MgO	H ² O
33.12	13.25	0.60	1.52	4.69	34.04	12.87 = 100.09
33.97	11.66	—	2.49	1.81	37.60	13.57 = 101.10

PENTADECANE. $C^{15}H^{32}$. *Benzyl Hydride*.—This hydrocarbon, obtained from American petroleum, has a sp. gr. of 0.825 at 19° , and boils at 258° to 262° . With chlorine it yields pentadecyl chloride, $C^{15}H^{31}Cl$ (Pelouze a. Cahours). When passed through red-hot tubes, it is for the most part converted into decane, $C^{10}H^{22}$ (Vohl, *Jahresb.* 1865, p. 841).

PENTADECENE. $C^{15}H^{24}$. *Benzylene*.—This hydrocarbon, homologous with ethine or acetylene, and related to benic acid, $C^{15}H^{26}O^2$, in the same manner as quintine or valerylene to valeric acid, is produced by heating triamylene acetate with potash:

It is a thickish, colourless, faintly smelling liquid, boiling at 230° – 240° . It unites with bromine, producing great rise of temperature, and, if well cooled, without perceptible evolution of hydrobromic acid (Bauer, *Ann. Ch. Pharm.* xxxvii. 249).

PENTAHIOLINE. $C^{15}H^{15}N$.—A homologue of chinoline occurring among the higher products of the dry distillation of cinchonine (C. Gr. Williams, *Laboratory*, i. 109).

PERIDOTE. Lechartier (*Compt. rend.* lxvii. 41; *Zeitschr. f. Chem.* [2] iv. 606) prepares peridotates and pyroxenes by mixing the required oxides with silica, introducing the mixture, together with anhydrous calcium chloride, into a graphite crucible contained within an earthen crucible, the intervening space being packed with charcoal powder, and igniting the mixture strongly for an hour or two. The fused mass when treated with water leaves the silicate in the crystalline form. For silicates containing iron and manganese, a clay crucible is used instead of the graphite crucible, and the

iron and manganese are introduced as sesquioxides. In this manner, peridot, $2\text{MgO} \cdot \text{SiO}_2$, and magnesium-iron peridot, $2(\text{MgO} ; \text{FeO}) \cdot \text{SiO}_2$, have been obtained, agreeing with the native minerals in specific gravity and crystalline form.

PERSEA. The oil obtained from the pulp of the ripe fruits of the Avocado pear (*Persea gratissima*) by exhaustion with ether, or by cold pressure, contains 70.9 p. c. olein and 21.9 (29.1 ?) palmitin (Oudemans, *Jahresb.* 1866, p. 696).

PERU BALSAM. The oily liquid which separates on agitating Peru balsam with potash or soda-ley—called *Peru balsam oil* by Stoltze, *cinnamin* by Frémy (i. 497)—may be separated by fractional distillation into three portions, viz. benzyl alcohol, $\text{C}^7\text{H}^7\text{O}$, passing over at about 200° ; benzylic benzoate, $\text{C}^7\text{H}^7\text{O}_2$, C^7H^7 , the principal portion, boiling at 303° – 304° ; and benzylic cinnamate, $\text{C}^9\text{H}^9\text{O}_2$, C^7H^7 , passing over at about the boiling point of mercury. The crude oil likewise contains small quantities of free cinnamic and benzoic acids, resulting from decomposition of the benzylic ethers by the alkali used in separating it, and equivalent to the free benzyl alcohol also contained in it.

Peru balsam appears to contain only a single resin, yielding by analysis 66.3 to 67.25 p. c. carbon, and 6.22 to 6.32 hydrogen (Kraut, *Ann. Ch. Pharm.* clii. 129). This resin, separated from the alkaline solution of the balsam by hydrochloric acid, is brown, has a faint odour of vanilla, and when fused with potash, yields protocatechuic acid, together with a little benzoic acid (Kachler, *Zeitschr. f. Chem.* [2] vi. 59).

PETALOSTIGMA. The stem-bark of *Petalostigma quadriloculare*, an Australian euphorbiaceous plant, contains, together with the ordinary plant-constituents, a camphoroid essential oil, and an indifferent bitter principle belonging to the glucosides. The ash of the bark (8.3 p. c.) contains 2.94 p. c. NaCl, 2.75 K_2O , 0.94 Na_2O , 46.23 CaO , 1.43 MgO , 0.05 Al_2O_3 , 0.18 Fe_2O_3 , 0.46 Mn_2O_3 , 1.32 SO_2 , 0.56 P_2O_5 , 2.21 SiO_2 , and 40.33 CO_2 (Falco, *Chem. Centr.* 1867, p. 142).

PELIZA. *Peliza eruginosa*, a fungus growing on wood, yields, when treated with nitric acid, a dark green solution, from which water precipitates light green flocks of a colouring matter identical in every respect with the xylochloric acid (v. 1060) extracted by Fordos from decayed wood (A. Crum-Brown, *Proc. Roy. Soc. Edinb.* v. 439).

PHÉORETIN. See RHUBARB.

PHELLYL ALCOHOL. See CORK (p. 496).

PHENACONIC ACID. $\text{C}^8\text{H}^7\text{O}^4$ (Carius, *Ann. Ch. Pharm.* cxlii. 129; *Jahresb.* 1866, p. 664; *Zeitschr. f. Chem.* [2] iv. 729; further, *Ann. Ch. Pharm.* cxlix. 257).—An acid, isomeric with acetic acid, produced by heating trichlorophenomalic acid (formed by the action of chlorous acid, ClHO_2 , on benzene) with baryta-water:

On removing the excess of baryta by carbonic acid, concentrating the filtrate, decomposing the barium phenaconate with sulphuric acid, evaporating, and recrystallising the residue from water, phenaconic acid is obtained in small prisms, needles, or broad laminae, with an amount of water probably corresponding to the formula $\text{C}^8\text{H}^7\text{O}^4 \cdot \text{H}^2\text{O}$; from alcohol it separates in more distinct crystals, probably monoclinal. The crystals effloresce on exposure to the air, becoming white like chalk: they give off all their water and partially volatilise at 130° , begin to sublime at 170° in acuminated prisms, and when gradually heated may be volatilised completely and without decomposition: the vapour excites coughing. When quickly heated to 220° , the acid decomposes, a film of water being deposited, from which a new acid crystallises by evaporation, the residue being carbonised. Phenaconic acid is sparingly soluble in cold water (100 pts. water dissolve 0.672 pt. of the acid at 16.5°), more easily in hot water, also in alcohol and in ether. It is but slowly attacked by oxidising agents in acid solution; boiling *nitric acid* converts it into oxalic acid; it does not appear to form a nitro-acid. Boiled in ammoniacal solution with *silver nitrate*, it gradually precipitates the silver.

By *hydriodic acid* it is wholly converted into ordinary succinic acid: $2\text{C}^8\text{H}^7\text{O}^4 + \text{H}^2 = 3\text{C}^4\text{H}^5\text{O}^4$.

Heated to about 100° in sealed tubes with *bromine*, in the proportion of $2\text{C}^8\text{H}^7\text{O}^4 : 3\text{Br}^2$, and about 20 times its weight of water, it is converted into bromomaleic and isobromomaleic acid (see *MALEIC ACID*, p. 797):

With a smaller quantity of water (6 to 10 pts.) dibromosuccinic acid is obtained, together with bromoform, hydrobromic acid, and carbon dioxide:

When the product of this last reaction is boiled with baryta-water, the dibromosuccinic acid is converted into paratartronic acid, identical in crystalline form and most of its properties with natural racemic acid:

Phenaconic acid is a strong acid containing 4 atoms of replaceable hydrogen. Its salts crystallise well, and are mostly composed according to the general formula: $\text{C}^6\text{H}^4\text{O}^4\text{R}^2$. With the alkali-metals it likewise forms salts containing 2 or 1 at. metal, but not double salts containing the alkali-metals together with other metals. These salts give off their water of crystallisation between 100° and 150° , and decompose at higher temperatures, leaving more or less charcoal, and giving off acid vapours smelling like acetic acid, without a trace of products containing less hydrogen. Free phenaconic acid is not precipitated by any of the ordinary reagents; the solutions of its ammonium and barium salts give with ferric chloride a brownish-yellow pulverulent precipitate; with cupric acetate no precipitate in the cold, but at the boiling heat green gelatinous flocks which redissolve on cooling. Silver nitrate and lead acetate slowly added to the solution, produce transient turbidity, and the liquid if then left at rest, deposits crystalline phenaconate of silver or lead; by an excess of the precipitant these salts are thrown down in the amorphous state.

The *potassium salts*, $\text{C}^6\text{H}^4\text{O}^4\text{K}^2$, $\text{C}^6\text{H}^4\text{O}^4\text{K}^2\text{H}$, and $\text{C}^6\text{H}^4\text{O}^4\text{KH}^2$, obtained by precipitating the barium salt with potassium sulphate, or partially with sulphuric acid, form hydrated easily soluble crystals. An *acid ammonium salt* remains on evaporating a solution of the acid neutralised with ammonia; an *ammonio-potassic salt*, $\text{C}^6\text{H}^4\text{O}^4\text{K}(\text{NH}) + \text{H}^2\text{O}$, is obtained in like manner by saturating the dipotassic salt with ammonia and evaporating. The *calcium salt*, $(\text{C}^6\text{H}^4\text{O}^4)^2\text{Ca}^2 + 4\text{H}^2\text{O}$, forms mucous tables and laminae like those of the oxalate; it is soluble in alcohol, and on rapid evaporation crystallises with 8 mol. water. The *barium salt*, $(\text{C}^6\text{H}^4\text{O}^4)^2\text{Ba}^2 + 4\text{H}^2\text{O}$, crystallises in tables and laminae, sometimes also in prisms; dissolves slowly in cold water (100 pts. water at 17° dissolve 0.9663 pt.); more quickly but not more abundantly in hot water. The *copper salt*, $\text{C}^6\text{H}^4\text{O}^4\text{Cu}^2 + 4\text{H}^2\text{O}$, separates on evaporating a solution of the acid saturated with cupric oxide, as a greenish indistinctly crystalline powder. The same salt is obtained in beautiful blue monoclinic tables on evaporating a solution containing the constituents of the soluble salt, $(\text{C}^6\text{H}^4\text{O}^4)^2\text{Cu}^2\text{K}^2$. The *lead salt*, $(\text{C}^6\text{H}^4\text{O}^4)^2\text{Pb}^2$ (at 120°), prepared as above described, crystallises in oblique rhombic tables and prisms. The *silver salt* forms microscopic tables and prisms, giving off water at 90° , and blackening both when heated in the dry state and when boiled with water (whereby it is abundantly dissolved); it is easily soluble in acetic and in phenaconic acid. With ethyl iodide it forms neutral *ethyl phenaconate*, $\text{C}^6\text{H}^4\text{O}^4.(\text{C}^2\text{H}^5)^2$, as an oily liquid having a faint odour, and distilling without decomposition. The same ether is formed by treating phenaconic chloride with alcohol; it is heavier than water, insoluble therein, and boils at 225° .

Phenaconic Chloride, $\text{C}^6\text{H}^4\text{O}^4.\text{Cl}^2$, produced by the action of phosphorus pentachloride on the acid, is a colourless liquid boiling at 165° , and decomposing at 250° ; it sinks in water and is immediately decomposed thereby, reproducing phenaconic acid. Vapour-density obs. 7.62 and 7.60; calc. = 7.952.

PHENETOL-SULPHURIC ACID. $\text{C}^6\text{H}^4\left\{\begin{smallmatrix} \text{OC}^2\text{H}^5 \\ \text{SO}^2\text{H} \end{smallmatrix}\right.$ —When phenetol (ethylphenol) is heated with an equal weight of strong sulphuric acid, the resulting crystalline mass dissolved in water, and the solution neutralised with baryta, a barium salt, $(\text{C}^6\text{H}^4.\text{OC}^2\text{H}^5.\text{SO}^2)^2\text{Ba}^2 + 4\text{H}^2\text{O}$, separates in tabular and lance-shaped crystals, nearly insoluble in cold, slightly soluble in hot water. The mother-liquor retains a very soluble barium salt of an isomeric acid, distinguished as *phenetolparasulphuric acid*, the salts of which are all amorphous, and therefore not well characterised. *Lead phenetolsulphate*, $(\text{C}^6\text{H}^4.\text{OC}^2\text{H}^5.\text{SO}^2)^2\text{Pb}^2$, obtained by neutralising the acid with lead carbonate, crystallises from the concentrated solution in cauliflower-like masses, the phenetolparasulphate remaining in solution. *Potassium phenetolsulphate*, $\text{C}^6\text{H}^4.\text{OC}^2\text{H}^5.\text{SO}^2\text{K} + \text{H}^2\text{O}$, crystallises in large silky needles easily soluble in cold water, slightly soluble in boiling alcohol. The *silver salt* is completely decomposed by evaporation, with separation of silver (Opl. a. Lippmann, *Compt. rend.* lxxiii. 1332).

PHENOL. $C^6H^6O = C^6H^5OH$. *Phenyl Hydrate. Phenyl Alcohol.*—This compound is formed: 1. By heating anisol with concentrated hydriodic or hydrochloric acid to 130° – 140° (Graebe, *Ann. Ch. Pharm.* cxxxix. 149):

2. By boiling the sulphate, nitrate, or hydrobromide of diazobenzene with water (Griess, *ibid.* cxxvii. 39):

3. By fusing potassium phenylsulphite with excess of potash (Wurtz, *Bull. Soc. Chim.* [2] viii. 197):

4. By heating acetylene with fuming sulphuric acid, whereby it is converted into the acid $C^6H^5SO^3$, and fusing the potassium salt of this acid with potash. The acetylene is then separated and polymerised, and the polymeric compound takes up oxygen, $3C^2H^2 + O = C^6H^5O$ (Berthelot, *Compt. rend.* lxviii. 539).

The phenol obtained by distilling oxybenzoic acid with lime (iv. 205) is identical with that produced in like manner from parabenzoic and salicylic acids, and with that obtained from coal-tar (Rosenthal, *Zeitschr. f. Chem.* [2] v. 627).

Preparation.—The following method of obtaining pure phenol from coal-tar is given by Hugo Müller (*Zeitschr. f. Chem.* [2] i. 270). The aqueous solution obtained by treating coal-tar with caustic soda or milk of lime, or a mixture of the two—which contains, besides phenol, certain easily oxidisable substances, and a not inconsiderable quantity of naphthalene—is diluted with water as long as naphthalene is thereby separated, and the liquid, which soon turns dark brown, is exposed to the air in shallow vessels for several days and frequently stirred. The brown solution is then filtered, the quantity of phenol contained in a given quantity of it is determined; and the quantity of acid required to precipitate the entire amount is calculated therefrom. If now $\frac{1}{3}$ to $\frac{1}{2}$ of this quantity of acid be added to the liquid with constant stirring, the resinous substances altered by the action of the air are first precipitated, together with larger or smaller quantities of cresol and xylol. A further addition of acid precipitates chiefly cresol, and after a few trials it is generally possible so to adjust the quantity of acid that the third and last precipitation shall yield nearly pure phenol, which crystallises after a single distillation. As even a small quantity of water prevents the crystallisation of phenol, it is necessary to remove this water completely by heating the phenol nearly to the boiling point, while a stream of dry air is passed over it. The crystallisation may be accelerated by cooling, or by the introduction of a small quantity of crystallised phenol. Crude phenol, such as is obtained from tar-refineries, may be conveniently purified by treating it several times in succession with soda-ley. The first extracts contain the purer product: the precipitation of the phenol must however be preceded by dilution with water and exposure to the air. A perfectly pure product, remaining colourless when preserved, is obtained only when the substances which turn brown by oxidation have been completely removed by exposure to the air. Phenol commonly contains a small quantity of a very disagreeably smelling sulphur-compound (phenyl sulphide), which may be removed by distillation over a small quantity of lead oxide.

For the preparation of crystallised phenol, Bickerdike (*Chem. News*, xvi. 188) recommends that the commercial product purified by one rectification be dehydrated with 1 or 2 p. c. of anhydrous cupric sulphate. The distillate solidifies for the most part at 16° , especially in contact with solid phenol.

Reactions.—1. An alcoholic solution of phenol is turned brown by an alcoholic solution of ferric chloride; wood-tar creosote similarly treated yields a solution of a fine emerald-green colour (Frisch, *J. pr. Chem.* c. 223:—Gorup-Besanez, *Ann. Ch. Pharm.* cxliii. 129).—2. When a few sticks of potash are immersed in a solution of phenol in chloroform, the potash becomes covered with a rose-coloured layer which gradually dissolves, the liquid becoming very hot and ultimately brown and viscid. The first product is a brown amorphous mass, soluble in alkalis, reprecipitated by acids, and apparently consisting of two substances, one of which dissolves very easily in alkaline carbonates, less easily in strong sulphuric acid; this latter solution gives with water, a precipitate exhibiting with alkalis the reactions of rosolic acid. The other substance is less soluble in alkalis, but dissolves very easily in strong sulphuric acid, and is not reprecipitated by water. If carbon tetrachloride be used as the solvent instead of chloroform, no reaction takes place in the cold, but at 180° the liquid assumes the colour of rosolic acid. When wood-tar creosote is treated in the same manner, a very similar reaction takes place, but the product is altogether

different, forming with sulphuric acid a deep crimson solution, from which water throws down a green precipitate. Moreover, the products obtained as above from phenol colour silk and wool brown in alkaline solution, whereas those from creosote exhibit no tinctorial power (C. Crump, *Chem. News*, xx. 126).

3. *Potassium permanganate* is immediately decolorised by aqueous phenol, and if the permanganate be added till the colour no longer disappears, the only products are carbonic and oxalic acids; by incomplete oxidation there is formed—besides a resin very near to phenol in composition—only oxalic acid in determinable quantity, together with extremely small quantities of resinous and syrupy bodies (Tollens, *Zeitschr. f. Chem.* [2] iv. 715).

4. Phenol-vapour passed over heated *zinc-dust* is easily reduced to benzene, together with small quantities of liquid and solid secondary products of higher boiling point.

5. Phenol heated with *carbon dioxide* under strong pressure yields crystals resembling rock-salt, of a compound probably containing $8C^6H^4O \cdot CO_2$ (Barth, *Ann. Ch. Pharm.* cxlviii. 49).

6. Phenol dissolves easily in an equal weight of strong *sulphuric acid*, producing two isomeric acids, $C^6H^4(OH) \cdot SO_3H$, distinguished as phenyl-parasulphuric and phenyl-metasulphuric acid (Kekulé, *Zeitschr. f. Chem.* [2] iii. 197) (see p. 923). When 2 pts. of crystallised phenol and 3 pts. hydrogen sulphate are heated for three or four hours to 160° , and the viscid product is poured into cold water, crystals of oxysulphobenzide, $C^{12}H^{10}SO_4$ (p. 894), are deposited (Glutz, *Ann. Ch. Pharm.* cxlvii. 52).

7. Phenol heated to 150° for three or four hours in sealed tubes with *sulphuryl chloride* is converted chiefly into monochlorophenol (Dubois, *Zeitschr. f. Chem.* [2] ii. 705):

8. According to Glutz (*Ann. Ch. Pharm.* cxliii. 180), a mixture of equal parts of phenol and *phosphorus pentachloride* heated to 100° for about three hours, and then distilled over the open fire, yields a large quantity of chlorobenzene or phenyl chloride, C^6H^5Cl . No phosphorus oxychloride is obtained, because it reacts with the phenol in such a manner as to form triphenylic phosphate:

Otto (*ibid.* cxlvii. 317) obtained by the same process only a very small quantity of phenyl chloride (compare iv. 390).

9. On adding *phosphoric anhydride* to pure liquefied phenol, a viscid syrup is formed, which, after standing for 24 hours at 40° , contains mono- and di-phenylic phosphate (Rembold, *Zeitschr. f. Chem.* [2] ii. 651).—10. Phenol distilled with pulverised *phosphorus pentasulphide* yields phenyl sulphhydrate, C^6H^5SH , and phenyl sulphide, $(C^6H^5)_2S$ (Kekulé a. Szuch, *Compt. rend.* lxiv. 752).

On the constitution of the compounds of phenol with bases, see Romei (*Bull. Soc. Chim.* [2] xi. 120; *Zeitschr. f. Chem.* [2] v. 383).

Bromophenols (Körner, *Ann. Ch. Pharm.* cxxxvii. 197).—*Monobromophenol*, C^6H^4BrOH , originally obtained by Cahours by distilling bromosalicylic acid with baryta, is also produced when air saturated with the vapour of 160 pts. bromine is passed into 94 pts. of cooled phenol (on passing the hydrobromic acid thereby evolved into water, the solution deposits after a while flocks and threads of nearly pure tribromophenol). The still impure monobromophenol remaining in the flask is washed with dilute soda-ley, reprecipitated by dilute hydrochloric acid, and the separated oil, after washing with water, is distilled under reduced pressure. The same compound may be prepared more quickly, though with greater loss, by carefully mixing a cooled solution of phenol in 6 to 8 pts. carbon bisulphide with bromine, and after removal of the solvent, purifying the product by distillation as above.

Monobromophenol is a colourless oily liquid, of sp. gr. 1.6606 at 30° , and boiling at 132° under a pressure of 22 mm., or at 118° under a pressure of 9 mm. It does not solidify at -18° ; is very easily coloured brown by dust, &c.; has an unpleasantly penetrating odour; instantly produces a white blister on the skin; is insoluble in water, but dissolves in all proportions of alcohol, ether, benzol, and carbon bisulphide. It unites with alkalis, forming salts which are very soluble in water. Heated with alcoholic potash to 160° – 180° it forms potassium rosolate, and with a large excess of potash, also phenol. Heated with 1 mol. sodium hydrate and methyl iodide to 100° – 120° , it is converted into *methylic monobromophenate*, $C^6H^4BrO \cdot CH_3$, a colourless mobile liquid having an ethereal odour, a burning aromatic taste, and boiling at 223° (corr.).

Dibromophenol, $C^6H^3Br^2OH$, is prepared in the same manner as monobromophenol, using the requisite quantities of the materials, and collecting apart the portion which distils at 154° under a pressure of 11 mm. It forms a crystalline mass having a satiny lustre and unpleasant odour, melting at 40° , and subliming even at ordinary temperatures. It distils quite undecomposed under reduced pressure, and for the most part also under the ordinary pressure; is nearly insoluble in water, but dissolves easily in alcohol, ether, benzol, and carbon bisulphide. By nitric acid it is easily converted into picric acid. Its potassium salt forms white deliquescent nodules. *Methylo dibromophenate*, produced by heating dibromophenol to 100° – 120° with caustic soda and methyl iodide, is identical with that which Cahours obtained by the action of bromine on anisol. It melts at 59° , boils at 272° , and crystallises from alcohol in nacreous scales, after fusion and partial cooling in large highly lustrous tables.

Tribromophenol, $C^6H^2Br^3.OH$, is easily formed by dropping bromine into phenol cooled at first, but afterwards gently warmed, as a crystalline mass, which when recrystallised from hot alcohol with addition of a little water, forms long silky needles, melting at 95° , easily subliming, nearly insoluble in water, easily soluble in alcohol, and uniting with bases to form salts, some of which crystallise well.

Tetrabromophenol, $C^6HBr^4.OH$, is produced by heating pure tribromophenol with 1 mol. bromine to 170° – 180° , and after repeated crystallisation and sublimation of the portion of medium solubility, forms concentric needles which melt at 120° , and dissolve very easily in alcohol.

Pentabromophenol, $C^6Br^5.OH$, is obtained by heating tetra- or tri- bromophenol with excess of bromine to 210° – 220° for several days, washing the product with water, and recrystallising it from carbon bisulphide. It dissolves but slowly in alcohol or carbon bisulphide, and crystallises from the latter in large adamantine needles, from the former in concentrically grouped needles, which melt at 225° , and sublime without decomposition when cautiously heated. With strong nitric acid it forms bromopicroin and bromanil, $C^6Br^5O^2$ (Körner).

Chlorophenols. **Monochlorophenol**, $C^6H^5Cl.OH$, is prepared: 1. By slowly passing chlorine into well-cooled phenol (500 grms.), distilling after about twelve hours, collecting apart the portion which goes over between 215° and 225° , and rectifying.—2. By the action of sulphuryl chloride on phenol (p. 907). It is a white crystalline body having a penetrating odour, melting at 41° , boiling at about 220° , soluble in alcohol, ether, benzol, and aqueous caustic alkalis, but not in alkaline carbonates (Dubois, *Zeitschr. f. Chem.* [2] iii. 205). Bähr-Predari (*ibid.* vi. 246), by passing chlorine into phenol mixed with a little water and cooled with ice, washing the product with weak potash-solution, dehydrating with calcium chloride and anhydrous cupric sulphate, then filtering and fractionating, has obtained a monochlorophenol melting at 8.5° and boiling at 220° . Heated with potash to 190° , it appears to yield hydroquinone.

Dichlorophenol, $C^6H^4Cl^2.OH$, previously known only as an oil (iv. 392), is obtained by passing dry chlorine into phenol, repeated fractional distillation, and recrystallisation from benzol, in colourless slender six-sided needles several inches long, exhibiting a pale reddish tint when dried and viewed in mass. It melts at 42° – 43° , boils at 209° , and does not therefore appear to correspond with monochlorophenol (which boils at 220°). It is nearly insoluble in water, but dissolves very easily in alcohol, ether, and warm benzol. It has an unpleasant odour, volatilises with vapour of water, and expels carbonic acid from alkaline and earthy carbonates when boiled with them in presence of water; in the cold, however, it is separated from these solutions by carbonic acid. Its *ammonium salt*, $C^6H^4Cl^2O(NH^4)$, crystallises from a hot solution of dichlorophenol in strong ammonia, in colourless shining needles; from dilute solutions in tables apparently rhombic. The *potassium salt* forms thin colourless rhombic tables, quickly becoming greyish-violet on exposure to light, especially when moist, easily soluble in water and alcohol, giving off the free acid even at 70° . The *silver salt* is a yellowish amorphous precipitate, quickly blackening, even in the dark. The *lead salt* (probably basic $C^6H^4Cl^2O.Pb.OH$), precipitated from the solution of the ammonium salt, is white and amorphous. The *ethylc ether*, $C^6H^4Cl^2OC^2H^5$, obtained by boiling the potassium salt with ethyl iodide, precipitating with water and rectifying, is a colourless oil boiling at 226° – 227° , nearly insoluble in water, miscible in all proportions with alcohol and ether (F. Fischer, *Zeitschr. f. Chem.* [2] iv. 386).

Another modification of dichlorophenol is obtained by passing nitrous acid vapour into a cooled mixture of dichlor-orthoamidophenol sulphate (p. 913) and dilute sulphuric acid, whereby diazodichlorophenol sulphate is separated as a light brown crystalline powder; heating this powder with water and sodium carbonate; and distilling the product with sulphuric acid. Dichlorophenol then separates from the distillate in

slender colourless needles (sometimes also as a faintly yellow oil) very slightly soluble in water, miscible in all proportions with alcohol and ether, having a disagreeable pungent odour, melting at 65°, and boiling between 218° and 220° (Seifart, *Zeitschr. f. Chem.* [2] v. 450).

Trichlorophenol, $C^6H^2Cl^3OH$ (iv. 392), produced by the action of dry chlorine on melted phenol, melts at 67°–68°, boils with slight decomposition at 243·5° to 244·5°, volatilises with vapour of water, and exhibits an acid reaction in alcoholic solution. Nitric acid converts it into dichloroquinone:

The salts produced by boiling trichlorophenol with the carbonates of the alkalis and alkaline earths have an alkaline reaction, and mostly give off trichlorophenol when gently heated. The *potassium salt*, $2C^6H^2Cl^3OK + H^2O$, is easily soluble in water, and crystallises in cauliflower-like masses, appearing under the microscope as fuscate groups of capillary needles. The *ammonium salt*, $C^6H^2Cl^3O(NH^4)$, crystallises in large somewhat sparingly soluble needles. The rather sparingly soluble *barium salt*, $(C^6H^2Cl^3O)^2Ba + 4H^2O$, crystallises in radiate groups of laminae, which give off their water at 140°. The easily soluble *magnesium salt*, $(C^6H^2Cl^3O)^2Mg + 2H^2O$, crystallises with difficulty in circularly grouped pointed needles. On mixing the alcoholic solution of trichlorophenol with neutral lead acetate, a *basic lead salt*, $2(C^6H^2Cl^3O)^2Pb.PbO$, separates in the crystalline form, while the *normal salt*, $(C^6H^2Cl^3O)^2Pb$, which crystallises in slender prisms, remains in solution. The *silver salt*, $C^6H^2Cl^3OAg$, is a yellow amorphous precipitate. The *ethyl ether*, $C^6H^2Cl^3OC^2H^5$, formed by boiling the potassium salt with ethyl iodide, crystallises in white prisms, melts at 43°–44°, boils at 240°, and is converted by a mixture of sulphuric and nitric acids into a body which crystallises in tufts of needles melting at 53°–54° (A. Faust, *Zeitschr. f. Chem.* [2] iii. 727).

Iodophenols. Schlützenberger a. Sengenwald obtained these compounds by the action of iodine chloride on phenol (iv. 394, 400). Körner (*Ann. Ch. Pharm.* cxxvii. 197) has prepared mono- and tri-iodophenol by treating phenol with iodine and iodic acid, in presence of free alkali and a dilute solution. *Mono-iodophenol*, C^6H^4IOH , is produced, according to the equation:

The iodine and iodic acid are first dissolved in the required proportions in dilute potash, the phenol is then added, and the liquid, while constantly stirred, is supersaturated with dilute hydrochloric acid. The precipitated oil, which contains mono-iodophenol, with a small quantity of the tri-iodated compound, is washed with water containing alcohol, and again precipitated from alkaline solution by hydrochloric acid. It is colourless, solidifies at low temperatures, has a strong disagreeable odour, and unites with alkalis, forming salts which are insoluble in concentrated alkali, and are decomposed by carbonic acid. Tri-iodophenol, C^6H^2IOH , prepared like the preceding compound with the required proportions of the materials, separates on acidulation with hydrochloric acid, as a greyish-white flocculent mass, and crystallises from alcohol of 50 p. c. in interlaced needles, or in large flattened needles like those of benzoic acid. It has a faint but unpleasant odour, melts at 150°, and decomposes when sublimed.

Mono-iodophenol (prepared as above), added to melting caustic potash mixed with so much water that it melts at 165°, is converted into a mixture of the isomeric compounds pyrocatechin and hydroquinone, $C^6H^4O^2$, the latter in the larger proportion, the change consisting in the replacement of I by HO. On precipitating with hydrochloric acid, agitating with ether, and evaporating, there remains a mixture of pyrocatechin and hydroquinone, which may be separated by precipitation with lead acetate (not in excess), the hydroquinone then remaining in solution.

Mono-iodophenol is likewise obtained, by a series of transformations, from nitraniline, namely, by converting this compound into diazonitrobenzene sulphate (iv. 448); this latter into iodonitrobenzene by the action of hydriodic acid: $C^6H^4(NO^2)N^2 + HI = C^6H^4(NO^2)I + N^2$; this into diazo-iodobenzene by the action of nitrous acid; and the diazo-iodobenzene into iodophenol by boiling its nitrate or sulphate with water: $C^6H^4IN^2 + H^2O = C^6H^4IO + N^2$. The iodophenol thus obtained from nitraniline is converted by melting potash wholly into hydroquinone; and that prepared in like manner from β nitraniline or paranitraniline (from dinitrobenzene) yields the isomeric compound resorcin. There are therefore three modifications of mono-iodophenol, yielding by substitution of HO for I, the corresponding modifications of oxyphenol: viz. *ortho-iodophenol* (1 : 2), yielding hydroquinone; *meta-iodophenol* (1 : 3), yielding pyrocatechin; and *para-iodophenol* (1 : 4), yielding resorcin.

The iodophenol obtained by the action of iodine and iodic acid on phenol is a mixture of ortho- and meta-iodophenols, the former predominating (Körner). See AROMATIC SERIES (p. 198).

Hlasiwetz & Weselsky (*Wien. Akad. Ber.* 1x. [2] 290; *Chem. Centr.* 1870, 63) prepare mono- and di-iodophenol by the action of iodine on phenol in alcoholic solution, in presence of an easily reducible metallic oxide which yields an insoluble iodide (mercuric oxide). For mono-iodophenol the proportions are those indicated by the equation:

but even when these proportions are exactly observed, di-iodophenol is always formed at the same time. The mono-iodophenol is found chiefly in the alcoholic filtrate; the di-iodophenol remains mixed with the mercuric iodide, and may be dissolved out by dilute solution of potassium carbonate, and precipitated by hydrochloric acid. The mono-iodophenol obtained by evaporating the alcoholic liquid yields by decomposition with potassium hydrate, chiefly resorcin (with a little pyrocatechin), and therefore consists mainly of para-iodophenol.

For the preparation of di-iodophenol the best proportions are indicated by the equation:

Crystallised from weak spirit, it forms colourless or slightly greyish, soft, felted crystals, having a silky lustre, and a faint but persistent odour, like that of mono-iodophenol; it dissolves easily in alcohol, ether, and carbon bisulphide; sublimes; melts at 150° ; and decomposes at a higher temperature. It is not decomposed by boiling with aqueous or alcoholic potash solution, but when fused with potassium hydrate it yields a considerable quantity of a brown viscid uncrystallisable substance containing a small quantity of pyrocatechin.

Nitrophenols. The crystalline and less volatile modification of mononitrophenol called *isonitrophenol*, which Fritzsche obtained by the action of nitric acid on aqueous phenol (iv. 395), is converted by reduction into an amidphenol, which, when oxidised with potassium chromate and sulphuric acid, yields large quantities of hydroquinone; it is therefore orthonitrophenol (1:2). The dinitrophenol prepared from this compound is identical both with that obtained from the more volatile mononitrophenol (iv. 394), and with that which Griess obtained by heating diazodinitrophenol in alcoholic solution. In like manner the two modifications of mononitrophenol yield only one and the same trinitrophenol, or picric acid, melting at $122\text{--}6^\circ$ (Körner). There is at present no evidence to show whether the more volatile mononitrophenol belongs to the meta- or the para- series; it is therefore more convenient still to distinguish the two known modifications as *nitro-* and *iso-nitrophenol* (Körner, *Zeitschr. f. Chem.* [2] ii. 662, 731; *Bull. Acad. Belg.* [2] xxiv. 166).

Mononitromethyl-phenol or *Mononitranisol*, $\text{C}^6\text{H}^4(\text{CH}_3)(\text{NO}_2)\text{O}$, formed by the action of methyl iodide in excess on the silver salt of nitrophenol, is a yellowish fragrant oil boiling at 265° ; it solidifies at 0° , melts again at 9° , has a sp. gr. of 1.249 at 26° , and volatilises easily with vapour of water. *Isonitromethyl-phenol* or *Isonitranisol*, prepared like the preceding from silver isonitrophenate, crystallises in large rhombic prisms, melting at 48° , boiling at $258\text{--}260^\circ$, and likewise volatilising with vapour of water. Both these compounds are also produced by direct nitration of anisol (Brunck, *Zeitschr. f. Chem.* [2] iii. 202).

Monoamidomethylphenol or *Anisidine*, $\text{C}^6\text{H}^4(\text{NH}_2)(\text{CH}_3)\text{O}$, produced by reduction of nitranisol with tin and hydrochloric acid, is a colourless oil, which remains liquid below 0° , boils at 216° , and has a sp. gr. of 1.108 at 26° . The hydrochloride, $\text{C}^6\text{H}^4(\text{NH}_2)(\text{CH}_3)\text{O} \cdot \text{HCl}$, crystallises in easily soluble rhombic tables. *Isoamidomethylphenol* or *Isoanidine*, $\text{C}^6\text{H}^4(\text{NH}_2)(\text{CH}_3)\text{O}$, crystallises from alcohol or ether in colourless prisms, melting at 52° , and volatilising without decomposition. The *hydrochloride* forms easily soluble prisms (Brunck, *loc. cit.*).

Dinitrophenol. $\text{C}^6\text{H}^4(\text{NO}_2)_2\text{O}$.—This compound is best prepared by gradually adding a very strong aqueous solution of phenol to commercial nitric acid (sp. gr. 1.4), with constant agitation, till the action becomes feeble. Dinitrophenol then separates in considerable quantity, and after washing with water and crystallisation from alcohol and water, forms thin faintly yellow tables and laminae, or (from water) nearly colourless, fibro-laminar masses. It volatilises at 70° , passes over also with vapour of water; dissolves in 21 pts. water at 100° , in 197 pts. at 18° , and in 7261 pts. at 0° . Its *silver salt*, $2\text{C}^6\text{H}^4(\text{NO}_2)_2\text{OAg} + \text{H}^2\text{O}$, forms yellow needles, blackened by light, insoluble in ether, slightly soluble in water and alcohol, detonating violently when heated. The *mercuric salt*, obtained by precipitation, forms slightly soluble yellow

needles. The *ferric salt*, obtained in like manner, crystallises in green laminae moderately soluble in water. The *nickel salt*, $C^6H^3(NO^2)_2O \cdot 2Ni + 8H^2O$, forms green needles. The *manganous salt*, $[C^6H^3(NO^2)_2O]_2Mn + 5H^2O$, crystallises in tufts of rose-coloured easily soluble needles. The *quinine salt*, $C^6H^3(NO^2)_2O \cdot C^{20}H^{24}N^2O^2 + 3H^2O$, is insoluble in ether, nearly insoluble in water, slightly soluble in alcohol, and crystallises from the latter in tufts of long orange-coloured needles, or from water in light yellow laminar masses. The *ethyl ether* (dinitrophenetol), $C^6H^3(NO^2)_2O \cdot C^2H^5$, formed by heating the silver salt with ethyl iodide, crystallises from alcohol in nearly colourless needles blackened by light (compare iv. 399). The *methylic ether* (dinitranisol), $C^6H^3(NO^2)_2O \cdot CH^3$, forms long very slender needles; the *amylie ether* is a heavy colourless oil. *Urea dinitrophenate* forms indistinctly crystalline masses. *Naphthalene dinitrophenate*, $C^6H^3(NO^2)_2O \cdot C^{10}H^8$, crystallises from a solution of the two bodies in alcohol or benzol, in yellow needles. It is soluble in ether and in hot water, and crystallises from the latter in microscopic colourless needles. By prolonged boiling with water, it is decomposed, with continued evolution of naphthalene (Gruner, *J. pr. Chem.* cii. 222).

Trinitrophenol or *Picric Acid*. $C^6H^3(NO^2)_3O$.—Pure picric acid melts, according to Körner, at 122.5° ; the commercial acid between 114° and 115° .

Casthelaz (*Chem. News*, xv. 140) describes a process for the testing of commercial picric acid, founded on the fact that the pure acid is soluble in ether and in benzol, whereas the impurities (oxalic acid and various salts) are insoluble in those liquids.

Picric acid digested with a concentrated aqueous solution of *iodine chloride* is converted into chloropierin and chloranil (Stenhouse, *Chem. Soc. J.* [2] ii. 366). Under other circumstances it is converted by the same reagent into chlorodinitrophenol (p. 913).

The following *metallic picrates* have been examined by D. Müller (*Pogg. Ann.* cxxiv. 103) [$NO^2 = X$]:

Manganous salt,	$(C^6H^2X^2O)^2Mn + 5H^2O$,	light yellow rhombic crystals.
Cupric salt,	$(C^6H^2X^2O)^2Cu + 16H^2O$,	green quadrate crystals.
Cadmium salt,	$(C^6H^2X^2O)^2Cd + 7H^2O$,	light yellow rhombic crystals.
Ferrous salt,	$(C^6H^2X^2O)^2Fe + 5H^2O$,	{ light brown crystals permanent below 100° .
Sodio-magnesian salt,	$\left\{ \begin{array}{l} (C^6H^2X^2O)^2Mg \\ 3C^6H^2X^2ONa \end{array} \right\} + 9H^2O$,	{ yellow cauliflower-like crystalline groups.
Sodio-ferrous salt,	$\left\{ \begin{array}{l} (C^6H^2X^2O)^2Fe \\ 6C^6H^2X^2ONa \end{array} \right\} + 12H^2O$,	" " "
Sodio-cobaltous salt,	$\left\{ \begin{array}{l} (C^6H^2X^2O)^2Co \\ 6C^6H^2X^2ONa \end{array} \right\} + 12H^2O$,	" " "
Sodio-nickel salt,	$\left\{ \begin{array}{l} (C^6H^2X^2O)^2Ni \\ 6C^6H^2X^2ONa \end{array} \right\} + 12H^2O$,	" " "
Sodio-zinc salt,	$\left\{ \begin{array}{l} (C^6H^2X^2O)^2Zn \\ 6C^6H^2X^2ONa \end{array} \right\} + 12H^2O$,	" " "
Sodio-cadmian salt,	$\left\{ \begin{array}{l} (C^6H^2X^2O)^2Cd \\ 6C^6H^2X^2ONa \end{array} \right\} + 12H^2O$,	" " "
Aluminium salt,	$4C^6H^2X^2O \cdot Al^2O^3 + 16H^2O$,	yellow needles.
Ferric salt,	$4C^6H^2X^2O \cdot Al^2O^3 + 16H^2O$,	reddish-yellow needles.

1 pt. of *potassium picrate* requires for solution: of water, 273.3 pts. at 0° , and 440.8 pts. at 20° ; of alcohol, 1138 pts. at 0° , and 735.5 pts. at 20° (Frisch, *J. pr. Chem.* c. 229).

Picrate of Triethylrosaniline is one of the varieties of aniline green (Alfraisso, *Dingl. pol. J.* clxxxvi. 324; *Jahresb.* 1867. p. 964).

Ethyl Picrate, $C^6H^2(NO^2)_2O \cdot C^2H^5$, is easily obtained by digesting dry silver picrate (prepared by mixing a hot solution of picric acid with silver carbonate, boiling for a few minutes and filtering) with five times its weight of ethyl iodide at 100° , distilling off the excess of the latter, and repeatedly treating the residue with hot alcohol. The ether, when washed and repeatedly crystallised from alcohol, forms slightly yellowish needles an inch or two long, becoming darker on exposure to light. It is somewhat soluble in hot water, also in ethyl iodide, common ether, carbon bisulphide, and benzol; melts at 78.5° , solidifies at 73° , and decomposes with slight detonation at a higher temperature (H. Müller a. Stenhouse, *Chem. Soc. J.* [2] iv. 235).

Picrates of Hydrocarbons.—Picric acid, as already shown by Fritzsche (iv. 405), affords characteristic reactions for the detection of certain hydrocarbons. For this purpose it is convenient to use an alcoholic solution of the acid saturated at 20° – 30° , and either: (1) add the hydrocarbon to the cold-saturated alcoholic solution; or

(2) mix the picric acid solution with a hot alcoholic solution of the hydrocarbon; or (3) dissolve the hydrocarbon, with aid of heat, in the picric acid solution. The following combine under these circumstances with picric acid: *Naphthalene* is the only solid hydrocarbon whose cold-saturated alcoholic solution is precipitated by picric acid. The compound forms delicate stellate groups of yellow needles, easily soluble in alcohol. *Retene* treated by method 2 or 3 forms similar needles of an orange-yellow colour. *Anthracene* also forms ruby-coloured needles still more soluble than the preceding; the red alcoholic solution is decolorised by addition of a little more alcohol. Other hydrocarbons contained in crude anthracene exhibit the same reaction, which appears to be peculiar to anthracene and its homologues. The hydrocarbon boiling at 260° which exists in crude anthracene, likewise forms, when dissolved in the alcoholic solution of picric acid at the boiling heat, a compound crystallising in orange-yellow needles. *Chrysene* forms a granular yellow precipitate, obtainable only by method 3, and consisting of microscopic needles united in scales. In presence of benzerythrene the scales pass into brown spherical groups of needles. *Benzerithrene* boiled with an alcoholic solution of picric acid deposits brown-yellow flocks on cooling. The forms of these compounds, when examined by the microscope, are characteristic of the individual hydrocarbons, and easily distinguished from those of picric acid itself, which sometimes separates out; they may also be obtained with mixtures, inasmuch as these mixtures, excepting that of chrysene and benzerithrene, still yield the picrates of the several compounds contained in them. In mixtures of hydrocarbons all of which combine with picric acid, the separation may in many cases be effected by fractional precipitation (Berthelot, *Bull. Soc. Chim.* [2] vii. 34).

BROMONITROPHENOL, $C^6H^4Br(NO^2)O$, obtained by the action of bromine on the more volatile nitrophenol, crystallises from alcohol in shining, yellow, sublimable laminae, easily soluble in alcohol and ether, melting at 88° . Its *potassium salt*, $C^6H^3Br(NO^2)OK + 2H^2O$, forms long pointed four-sided needles, of a blood-red colour, moderately soluble in water, drying up over sulphuric acid to a dark red powder. The *barium salt*, $[C^6H^3Br(NO^2)O]^2Ba$, crystallises in anhydrous scales of dark red colour and golden lustre. The *silver salt*, $C^6H^3Br(NO^2)OAg$, forms a dark red precipitate or blood-red laminae having a golden lustre. *Bromisonitrophenol*, $C^6H^4Br(NO^2)O$, produced by the action of 1 mol. bromine on isonitrophenol, is not volatile without decomposition, and crystallises from aqueous alcohol or from ether in long satiny needles melting at 102° . The easily soluble potassium salt forms red crystalline crusts; the sodium salt lemon-yellow needles; the silver salt slender red needles (Brunck).

Dibromonitrophenol, $C^6H^3Br^2(NO^2)O$, is obtained (together with bromopicrin) by adding dibromophenol to a cooled mixture of nitric and sulphuric acid; when separated from its potassium salt and recrystallised from alcohol, it forms large easily sublimable prisms melting at 119° . Its *potassium salt*, $C^6H^2Br^2(NO^2)OK$, forms scarlet needles slightly soluble in cold water, more soluble in boiling water and in alcohol; the *barium salt* is an orange-red, the *silver salt* a brown-red precipitate. The *methylic ether*, precipitated by water from a solution of methylic dibromophenolate in fuming nitric acid, crystallises from alcohol in colourless needles (Körner, *Ann. Ch. Pharm.* cxxxvii. 197; *Zeitschr. f. Chem.* [2] ii. 148). *Dibromisonitrophenol*, $C^6H^2Br^2(NO^2)O$, produced by the action of 2 mol. bromine on isonitrophenol, forms beautiful prismatic crystals sparingly soluble in water, easily in alcohol and ether, melting at 141° , and decomposing at a slightly higher temperature without subliming; the *potassium salt* in tufts of orange-yellow anhydrous needles, or in light yellow laminae containing 2 mol. water; the *barium salt*, $[C^6H^2Br^2(NO^2)O]^2Ba + 10H^2O$, in light yellow needles which crumble to a red powder; the *silver salt*, $C^6H^2Br^2(NO^2)OAg$, forms sparingly soluble yellowish needles (Brunck, *loc. cit.*).

CHLORONITROPHENOLS.—*Mononitrochlorophenol*, $C^6H^4Cl(NO^2)O$, is prepared by passing 200 grms. of chlorine gas into 500 grms. pure phenol not cooled, and gradually adding the resulting chlorophenol to 1000 grms. nitric acid of sp. gr. 1.4, previously diluted with 1500 grms. water. The mixture is left for four days, being frequently stirred, but not heated; the chloronitrophenol which collects at the bottom in lumps is collected, washed, and converted into sodium salt; this salt, after recrystallisation, is decomposed with hydrochloric acid; and the chloronitrophenol thereby separated is distilled with vapour of water and purified by recrystallisation from hot alcohol, ether, and chloroform. It crystallises from hot alcohol in needles; from chloroform in large light yellow triclinic prisms having the form of cupric sulphate; has a strong saffron-like odour, and melts at 86° – 87° . It dissolves easily in chloroform and ether, less easily in alcohol, and is nearly insoluble in water. Its salts crystallise easily and well, dissolve sparingly in cold, more easily in hot water. The

ammonium salt, $\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)\text{ONH}^4$, forms long orange-red needles, volatilising with vapour of water; the *sodium salt*, $\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)\text{ONa} + \text{H}^2\text{O}$, crystallises in red prisms; the *barium salt*, $[\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)\text{O}]^2\text{Ba} + 2\text{H}^2\text{O}$, in short red prisms; the *silver salt*, $\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)\text{OAg}$, in brownish-red needles, very slightly soluble in water. The *ethylic ether*, $\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)\text{OC}^2\text{H}^5$, obtained by heating the silver salt with ethyl iodide, crystallises in yellowish-white needles or laminae, having an unpleasant odour, and melting at $61^\circ\text{--}62^\circ$ (Faust a. Saame, *Zeitschr. f. Chem.* [2] v. 450).

Chloramidophenol Hydrochloride, $\text{C}^6\text{H}^3\text{Cl}(\text{NH}^2)\text{O.HCl}$, separates from the cooled solution obtained by reducing chloronitrophenol with tin and hydrochloric acid, and may be purified by recrystallisation from hot water. It crystallises in white laminae easily soluble in water and permanent in the air. The corresponding *sulphate* forms stellate groups of needles (Faust a. Saame).

Dichloronitrophenol, $\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)\text{O}$, obtained by adding crystalline dichlorophenol (p. 908) to fuming nitric acid, precipitating with water, and recrystallising from alcohol, appears to be identical with the nitro-compound which Laurent obtained in like manner from liquid dichlorophenol (iv. 397). It forms yellow crystalline laminae, melting at $121^\circ\text{--}122^\circ$, sparingly soluble, but with deep yellow colour, in water, sublimes slowly at 100° , and detonates when suddenly heated. Its *ammonium salt*, $\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)\text{ONH}^4$, crystallises in shining, deep orange-coloured, sublimable needles; a small quantity of its dust excites violent sneezing. The *sodium salt* forms nodular groups of orange-red needles; the *potassium salt*, long shining needles having nearly the colour of chromic acid. The *silver salt* crystallises from a large quantity of boiling water in tufts of very dark red needles. The *magnesium* and *barium salts* form silky orange-yellow needles, slightly soluble in water. The *basic lead salt*, $\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)\text{O.Pb.OH}$, is an orange-coloured precipitate. The *ethylic ether*, $\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)\text{O.C}^2\text{H}^5$, obtained by adding ethylic dichlorophenolate to fuming nitric acid, crystallises from absolute alcohol in large, flattened, nearly colourless prisms, melting at 29° . Dichloronitrophenol digested with tin and hydrochloric acid yields a double stannous salt (colourless when freshly prepared), which after separation of the tin by hydrogen sulphide, yields *dichloramidophenol hydrochloride*, $\text{C}^6\text{H}^2\text{Cl}^2(\text{NH}^2)\text{O.HCl}$, in colourless laminae, quickly reddening on exposure to light, easily soluble in water and alcohol. *Dichloramidophenol*, $\text{C}^6\text{H}^2\text{Cl}^2(\text{NH}^2)\text{O}$, separated therefrom, forms small white silky crystals which decompose very easily, especially when moist (Fischer, *Zeitschr. f. Chem.* [2] iv. 386).

Faust a. Saame have obtained dichloronitrophenol, with properties exactly the same as those above described, by passing 1 at. chlorine into monochloronitrophenol. Its *barium salt* forms orange-yellow needles containing $[\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)\text{O}]^2\text{Ba} + 2\text{H}^2\text{O}$.

Dichloro-isornitrophenol or *Dichloro-orthonitrophenol*, $\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)\text{O}$, is obtained by saturating fused orthonitrophenol with chlorine, and may be purified by converting it into a barium salt, recrystallising this salt several times, with addition of animal charcoal, and decomposing it with hydrochloric acid. When separated from a warm solution, it forms a heavy, nearly colourless, easily crystallising oil; dissolves easily in alcohol, ether, and chloroform, crystallises from ether in long slightly yellowish rhombic prisms or tables, from chloroform in flat shining colourless needles. Heated with water it melts, but is not perceptibly dissolved. It has a faint phenolic odour, does not volatilise with vapour of water, and is but slightly sublimable. Melts with decomposition at 125° . Its *ammonium salt*, $\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)\text{ONH}^4 + \text{H}^2\text{O}$, forms long shining yellow needles, which give off their water and become colourless when left over sulphuric acid; dissolves easily in hot, sparingly in cold water. The *sodium salt*, $\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)\text{ONa} + 5\text{H}^2\text{O}$, forms yellow shining needles, easily soluble in water and alcohol. The *barium salt*, $[\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)\text{O}]^2\text{Ba} + 4\text{H}^2\text{O}$, crystallises, according to concentration, in brown-red metallicallly lustrous prisms or laminae, or in light-red flat needles; dissolves easily in boiling water, sparingly in cold water. The *calcium salt*, $[\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)]^2\text{Ca} + 9\text{H}^2\text{O}$, crystallises in golden-yellow shining needles or laminae very soluble in water; the *magnesium salt*, $[\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)\text{O}]^2\text{Mg} + 10\text{H}^2\text{O}$, in rosettes of yellow needles, very soluble in water. The *silver salt*, $\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)\text{OAg}$, forms colourless interlaced needles, quickly turning yellow, and very sparingly soluble in water. The *lead salt*, $[\text{C}^6\text{H}^2\text{Cl}^2(\text{NO}^2)\text{O}]^2\text{Pb} + 4\frac{1}{2}\text{H}^2\text{O}$, forms very sparingly soluble, serrated, dull yellow needles, which easily give off their water. The *copper salt* forms dingy green needles, decomposing even below 100° . The *ethylic ether*, obtained from the silver salt by means of ethyl iodide, is a colourless body very much like phenol, melting at 136° (Seifert, *Zeitschr. f. Chem.* [2] v. 449).

Dichloro-orthoamidophenol, $\text{C}^6\text{H}^2\text{Cl}^2(\text{NH}^2)\text{O}$, obtained by reducing the dichloronitro-compound with tin and hydrochloric acid, crystallises from water in sparingly soluble colourless striated laminae, which easily turn brown. It dissolves easily in

alcohol, sublimates in colourless laminae when very slowly heated, melts at 165° – 166° . The *sulphate*, $[\text{C}^6\text{H}^3\text{Cl}^2(\text{NH}^2)\text{O}]^2 \cdot \text{SO}^2\text{H}^2 + 3\text{H}^2\text{O}$, crystallises from a boiling saturated aqueous solution in needles slightly soluble in hot alcohol. The *hydrochloride*, $\text{C}^6\text{H}^3\text{Cl}^2(\text{NH}^2)\text{O} \cdot \text{HCl}$, also crystallises in needles, decomposing easily in solution, melting below 230° , subliming completely in white laminae (Seifart).

Chlorodinitrophenol. $\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)^2\text{O}$.—This compound is known in two modifications, which may be distinguished as α and β . α *Chlorodinitrophenol* is obtained by the action of nitric acid on monochlorophenol (Dubois, *Zeitschr. f. Chem.* [2] iii. 205), or by adding monochloronitrophenol to red nitric acid (Faust a. Saame, *ibid.* v. 451). It crystallises from alcohol in yellow needles, from chloroform in large monoclinic prisms resembling sugar-candy, and has a great tendency to form twin-crystals. It melts at 81° , resolidifies at 69° , volatilises without decomposition when slowly heated, dissolves sparingly in cold, more easily in boiling water.

β *Chloronitrophenol* was obtained by Faust a. Saame from the residue left after the mononitrochlorophenol, prepared as above described, had been distilled off with aqueous vapour. This residue was added to red nitric acid, the dark solution precipitated by water, the precipitate converted into an ammonium salt; and this salt after repeated crystallisation was decomposed by hydrochloric acid. β chloronitrophenol thus obtained crystallises from hot water and dilute alcohol in yellowish laminae, from chloroform in irregular six-sided prisms melting at 111° . It is more soluble in hot water than the α modification. The *ammonium salt*, $\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)^2\text{ONH}^4 + \text{H}^2\text{O}$, crystallises in yellow needles; the *barium salt*, $[\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)^2\text{O}]^2\text{Ba} + 9\text{H}^2\text{O}$, in short yellow needles, brick-red when dehydrated. The *silver salt*, $\text{C}^6\text{H}^3\text{Cl}(\text{NO}^2)^2\text{OAg} + \text{H}^2\text{O}$, separates from hot water in a bulky mass of slender yellow needles. These salts are likewise more soluble in hot than in cold water.

γ *Chlorodinitrophenol*, the modification which Griess obtained by passing a strong stream of chlorine into phenol, and adding the product by small portions to nitric acid of ordinary strength (iv. 400), is more easily prepared, according to Stenhouse (*Chem. Soc. J.* [2] v. 435), by the action of iodine chloride on picric acid. Chlorine gas is passed into a mixture of 8 pts. picric acid, 3 pts. water, and 1 pt. iodine, kept in gentle ebullition in a flask provided with an upright condensing tube, till carbon dioxide and nitrogen dioxide are given off and no more oily drops of chloropierin are produced. The iodine chloride having been distilled off at 120° , the crystalline residue is washed with cold water and recrystallised from hot water. The chlorodinitrophenol thus obtained crystallises in yellow laminae melting at 103° , volatilising slightly at 100° , more easily with aqueous vapour.

On the constitution of the chloronitrophenols, see Petersen (*Ann. Ch. Pharm.* [1871] cxlvii. 171; *Chem. Soc. J.* [2] ix. 248).

IODONITROPHENOLS (Körner, *Bull. Acad. Belg.* [2] xxiv. 166; *Jahresh.* 1867, p. 616).—These compounds are formed by treating the nitrophenols in alkaline solution with a mixture of iodine and iodic acid, in proportions indicated by equation I. for the mono-iodated, and by equation II. for the di-iodated compounds:

They are precipitated from these solutions by hydrochloric acid in the form of powder, or in fused yellowish masses; if iodine still separates, the mixture must be once more supersaturated with alkali.

Iodisonitrophenol or *Iodorthonitrophenol*, $\text{C}^6\text{H}^3\text{I}(\text{NO}^2)\text{O}$, crystallises from a hot-saturated aqueous solution in yellow needles, melting at 93° , at a lower temperature under water, not volatile without decomposition. It is also formed by the action of hydriodic acid on diazonitrophenol, but when thus prepared it can be obtained pure (melting at 94°) only by repeated crystallisation from boiling carbon bisulphide. Its easily soluble *potassium salt* crystallises from water in yellow needles, from alcohol with 3 mol. water, in lemon-yellow prisms. The *sodium salt*, $2\text{C}^6\text{H}^3\text{I}(\text{NO}^2)\text{ONa} + 5\text{H}^2\text{O}$, forms golden-yellow elliptic scales; the *barium salt*, reddish-yellow needles; the *silver salt* is a lemon-yellow precipitate somewhat soluble in hot water, and crystallising therefrom in needles. *Iodonitrophenol* from volatile nitrophenol is golden-yellow, and crystallises readily, but has not been further examined.

Di-iodisonitrophenol, $\text{C}^6\text{H}^3\text{I}^2(\text{NO}^2)\text{O}$, crystallises from ethereal solution in colourless prisms, which turn yellow on exposure to the air, melt at 156° , and decompose at a higher temperature. The *potassium salt*, $\text{C}^6\text{H}^3\text{I}^2(\text{NO}^2)\text{OK}$, forms golden-yellow needles with violet iridescence; the *sodium salt*, orange-yellow recent laminae; the *silver salt* is a yellowish, nearly insoluble precipitate. *Di-*

nitrophenol (from volatile nitrophenol) crystallises from a mixture of alcohol and ether in slender dark-yellow needles; from ether in large prisms having a glassy lustre. It is slightly soluble in water, melts at 98°. The easily soluble *potassium salt*, $C^6H^4(NO^2)OK$, crystallises in red-brown needles; the *sodium salt*, $C^6H^4(NO^2)ONa + H^2O$, from alcoholic solution in dark brown prisms having a golden lustre, and yielding a blood-red powder; the silver salt is a black-brown precipitate.

Iodobromonitrophenol, $C^6H^3IBr(NO^2)O$, prepared from bromoisnitrophenol by the general process above given, is insoluble in water, slightly soluble in alcohol, easily soluble in ether, and crystallises from this solution in colourless prisms. The *potassium salt*, $C^6H^3IBr(NO^2)OK$, forms tufts of yellow needles. **Iodobromonitrophenol** (from volatile nitrophenol) crystallises from ether in orange-coloured prisms, melts at 104.2°, and volatilises with vapour of water. Its salts are sparingly soluble; the *potassium salt* crystallises in anhydrous flat prisms having a brown colour and bright metallic lustre; the *sodium salt* with 1 mol. water in dark brown prisms; the *barium, lead, and silver salts* are dark brown precipitates.

Iodo-dinitrophenol, $C^6H^3I(NO^2)_2O$, is nearly insoluble in water, soluble in alcohol and ether, and crystallises from alcoholic solution in vitreous sulphur-yellow prisms. It melts under boiling water and volatilises with aqueous vapour. The *potassium salt*, $C^6H^3I(NO^2)_2OK + 2H^2O$, crystallises from aqueous solution in yellow laminae or needles; the *barium salt* in yellow, slightly soluble laminae. A similarly composed and probably identical compound is produced by the action of hydriodic acid on diazodinitrophenol; but its potassium salt crystallises in orange-red anhydrous needles.

From the results just described, and from those obtained by Brunck with the bromonitrophenols (p. 912), Körner concludes: (1) That the places occupied by the nitroxyl in dinitrophenol are those which it occupies in isonitrophenol and in volatile nitrophenol; (2) that in the partial reduction of dinitrophenol, that atom of nitroxyl which corresponds to volatile nitrophenol gives place to amidogen; and (3) that in volatile nitrophenol the nitroxyl occupies one of two places, symmetrically situated with regard to the hydroxyl [that is to say, that it belongs to the meta-series].

Reduction-derivatives of the Nitrophenols: Amidophenols.

The amidophenols obtained by reduction of mononitrophenol and its chlorinated derivatives have been already noticed (pp. 910, 913).

From trinitrophenol or picric acid three amidophenols may be derived, viz.,

The first, generally known as *picramic acid*, was obtained by Girard in 1853, by reducing picric acid with hydrogen sulphide. According to C. D. Braun (*Zeitschr. f. Chem.* [2] i. 744), it is produced from picric acid by the action of potassium ferrocyanide, and more quickly in presence of alkali, by grape-sugar. Petersen (*Zeitschr. f. Chem.* [2] iv. 377) has examined some of its compounds with acids. The *hydrochloride*, $C^6H^3(NO^2)_2(NH^2)O.HCl$, separates from a hot-saturated solution in concentric groups of red-brown needles, soluble in alcohol and ether, giving off their hydrochloric acid partially on exposure to the air, completely at 80°. The *platinichloride*, $2(C^6H^3(NO^2)_2(NH^2)O.HCl).PtCl_4$, separates from concentrated solution in small yellow granular crystals. The *nitrate*, obtained by decomposing the hydrochloride in alcoholic solution with silver nitrate, crystallises in brown-red laminae. When a solution of amidodinitrophenol in cold strong sulphuric acid is diluted with water, the amidodinitrophenol is precipitated, and the solution yields brown crystals containing sulphuric acid.

Girard and Pugh found that picramic acid is converted by nitric acid into picric acid; but according to Wöhler and Carey Lea, this is not the case (iv. 406). Stenhouse (*Chem. Soc. J.* [2] vi. 150), by treating 1 pt. picramic acid with 3 pts. boiling nitric acid of sp. gr. 1.45, has obtained crystals of diazodinitrophenol, $C^6H^3N^2(NO^2)_2O$, together with a comparatively small quantity of picric acid, which remains in the mother-liquor.

Lautemann (iv. 640), by treating picric acid with iodine and phosphorus, obtained the hydriodide of picramine, $C^6H^3(NH^2)_3$, a base derived from picric acid by substitution of $(NH^2)^3$ for $(NO^2)_3$, and simultaneous reduction of the hydroxyl-group HIO ; and according to Beilstein (*Ann. Ch. Pharm.* cxxx. 242), the same base is obtained by reduction of picric acid with tin and hydrochloric acid. Heintzel (*Zeitschr. f. Chem.* [2] iii. 339) finds that the base obtained by either of these modes of reduction is not picramine, but tri-amidophenol, while, on the other hand, Gauhe (*ibid.* iv. 80) confirms Lautemann's results as to the formation of picramine hydriodide,

$C^6H^3(NH^2)^3.3HI$, by the action of iodine and phosphorus on picric acid, and regards the salt which Heintzel obtained by the same process, not as the hydriodide of triamidophenol, but as the trihydriodide of picramine contaminated with phosphoric acid.

Triamidophenol. $C^6H^2(NH^2)^3OH$.—A mixture of 1 pt. picric acid, 4 pts. tin, and 15 pts. crude hydrochloric acid, when gently warmed, begins to boil in a few minutes, and the filtered liquid deposits on cooling quadratic laminae, which after drying over lime in a vacuum, have, according to Heintzel, the composition of *triamidophenol stannochloride*, $C^6H^2(NH^2)^3OH.3HCl.SnCl^2$ [according to Beilstein, that of picramine stannochloride, $C^6H^2(NH^2)^3.3HCl.SnCl^2$]. This salt dissolves in water, alcohol, and ether, and after recrystallisation from water contains $1\frac{1}{2}$ mol. water (5.8 p. c.). It is partially decomposed by repeated crystallisation from a slightly acid aqueous solution, but from a solution containing a large excess of hydrochloric acid it separates without decomposition in fan-shaped groups of long needles. The alcoholic or ethereal solution of the salt acquires a deep blue colour; so likewise does the aqueous solution when much diluted; ferric chloride produces the same colour. The *hydrochloride*, $C^6H^2(NH^2)^3OH.3HCl$, obtained by removing the tin from the preceding salt by hydrogen sulphide, is easily soluble in water, less soluble in alcohol and ether, and separates by slow evaporation in a vacuum, in nodular groups of yellow needles; the concentrated solution imparts a permanent green-black colour to the skin, also to wool and silk. The *sulphate*, $2C^6H^2(NH^2)^3OH.3SO^2H^2$, is deposited on mixing the concentrated solution of the hydrochloride with dilute sulphuric acid, in white curly flocks, which when moist gradually change to dark-coloured rhombohedral crystals. The *hydroferrocyanide*, $2C^6H^2(NH^2)^3OH.Fe^2H^4Cy^6$, is a white crystalline precipitate, slightly soluble in water and in alcohol; potassium ferrocyanide also forms a white precipitate.

Amido-diimidophenol Hydrochloride, $C^6H^2(NH^2)(NH)^2OH.HCl^*$ (?), is gradually deposited from a concentrated solution of triamidophenol hydrochloride, in brown crystals having a blue lustre by reflected light, insoluble in ether, slightly soluble in alcohol, easily and with splendid blue colour in water; decomposed by hot water. The blue solution heated with dilute hydrochloric or sulphuric acid becomes red, and deposits white needles, having nearly the composition of the *hydrochloride of amid-imid-hydroxyphenol*, $C^6H^2(NH^2)(NH)(OH)^2.HCl^*$ (?) (Heintzel).

PHENOLIC ETHERS. *Ethyl-phenol* or *Phenetol*. $C^8H^{10}O = C^6H^5.(C^2H^5)O$ (Fittig u. Kiesow, *Zeitschr. f. Chem.* [2] v. 333. Beilstein u. Kuhlberg, *ibid.* 461; *Chem. Centr.* 1870, 45).—This compound, originally obtained by the dry distillation of barium ethyl-salicylate (iv. 391), may also be prepared by heating the potassium salt of ethyl-benzene-sulphuric acid with 3 pts. of potassium hydrate to 270° – 280° for some hours, acidulating with sulphuric acid, and distilling. The ethyl-phenol, which passes over with the first portions of aqueous vapour, is separated from the water, left some time in contact with calcium chloride, and subjected to fractional distillation, the greater part passing over between 208° and 210° . This portion solidifies on cooling in large transparent prismatic crystals, very much like phenol, which may be freed from an adhering viscid oil by pressure between bibulous paper in the exsiccator. The crystalline compound is ethyl-phenol. It melts at 47° – 48° and boils at 209° – 210° (Fittig u. Kiesow); melts at 46° and boils at 214° – 215° (Beilstein u. Kuhlberg), but volatilises even at ordinary temperatures. In contact with water it instantly liquefies, whence it seems to follow that liquid ethyl-phenol (iv. 391) is rather a hydrate than an isomeric modification (Fittig u. Kiesow). On the other hand, the liquid ethyl-phenol expressed from the crystals as above mentioned does not solidify even in a freezing mixture; it boils at 212° (Beilstein u. Kuhlberg).

Ethyl-phenol treated with sodium and carbon dioxide is converted into ethyl-(para- or meta-) oxybenzoic acid: $C^6H^5(C^2H^5)O + CO^2 = C^6H^5(C^2H^5)O^2$ (Beilstein u. Kuhlberg). See *PARAOXYBENZOIC ACID* (p. 899).

Methyl-phenol. $C^8H^9(CH^3)O$.—See *ANISOL* (i. 305).

Chloromethyl-phenol, $C^6H^4Cl(CH^3)O$, is produced by the action of phosphorus pentachloride on anisol. It is a colourless liquid having a rather agreeable odour, a sp. gr. of 1.182 at 9° , and boiling at about 200° . Insoluble in water and in alkalis, soluble in alcohol and in ether; dissolved by strong nitric acid with rise of temperature, but without evolution of gas (L. Henry, *Zeitschr. f. Chem.* [2] vi. 247).

Bromomethyl-phenol, $C^6H^4Br(CH^3)O$, obtained in like manner, boils at 220° , and has a sp. gr. of 1.194 at 9° (Henry).

Chlorethyl-phenol, $C^6H^4Cl(C^2H^5)O$, resembles the methyl-compound in external character, boils at 210° , and has a sp. gr. of 1.106 at 9° (Henry).

* These formulae are inadmissible, inasmuch as the imidogen, which is essentially a bivalent radical, enters into them as univalent.

Ethylene-diphenol. $C^{12}H^{10}O^2 = C^{12}H^{10}(C^6H^4)^2O^2$ (Lippmann, *Chem. Centr.* 1780, p. 45. *Burr, Zeitschr. f. Chem.* [2] v. 165).—Produced by heating 1 mol. ethylene bromide with 2 mol. finely pulverised potassium-phenol in a sealed tube to 140° . Forms small laminae, melting at 98.5° (Burr), 95° (Lippmann), and burning with a very smoky flame when heated on platinum foil. Insoluble in water, slightly soluble in cold alcohol, easily in boiling alcohol and cold chloroform (Lippmann); soluble also in ether, from which it separates in shining imperfectly developed crystals (Burr). When heated with strong nitric acid it is converted into an acid compound crystallising in needles of a deep yellow colour, and soluble in ether (Burr).

Ethylene-diphenol tetrabromide, $C^{12}H^{10}O^2Br^4$, is produced by dropping bromine into a solution of ethylene-diphenol in chloroform, heating the product for some hours to 100° , and crystallising from hot chloroform. It forms small interlaced needles melting above 100° .

Ethylene-diphenol-sulphuric acid, $C^{12}H^{14}S^2O^8 = C^{12}H^4(C^6H^4)^2(SO^3H)^2$, is formed by adding strong sulphuric acid to ethylene-diphenol heated to 120° , and keeping the mixture for some time at 100° . On saturating the liquid with lead carbonate, filtering, washing with hot water, and evaporating, the *lead salt*, $C^{12}H^4(C^6H^4)^2Pb$ (at 120°), crystallises in laminae soluble in hot water. The *barium salt* is a fine crystalline powder slightly soluble in hot water (Lippmann).

Isopropyl-phenol, $C^9H^8(C^3H^7)O$, is obtained by heating isopropyl iodide with sodium-phenol, either to 110° – 120° in sealed tubes, or in a retort with reversed condenser. When purified by precipitation with water, washing with potash-solution, and distillation, it forms a colourless, rather viscid liquid, smelling somewhat like geraniums. It boils at 176° , and has a sp. gr. of 0.958 at 0° , 0.947 at 12.5° . Vapour-density obs. = 5.00; calc. = 4.73. Index of refraction for the yellow sodium line = 1.5124. Inactive to polarised light.

Isopropyl-monobromophenol, $C^9H^7Br(C^3H^7)O$, is the chief product formed by gradually adding 1 mol. bromine to 1 mol. isopropyl-phenol. It is a somewhat viscid liquid, smelling like anisol, insoluble in water, soluble in alcohol, and more easily in ether. Boils at 236° . Sp. gr. = 1.981 at 0° ; 1.957 at 12.5° . Index of refraction for the yellow sodium line = 1.553. Inactive to polarised light.

By using an excess of bromine, more highly brominated products are obtained. The resulting crystalline mass dissolves completely in potash, and on adding hydrochloric acid, tribromo-isopropyl-phenol is precipitated, melting at 93° (Silva, *Bull. Soc. Chim.* [2] xiii. 27; *Zeitschr. f. Chem.* [2] vi. 249).

PHENOMALIC ACID. $C^6H^4O^3$ (Carius, *Ann. Ch. Pharm.* cxlii. 129; *Jahresb.* 1866, p. 560).—An acid homologous with malic acid, produced by reduction of trichlorophenomal'ic acid (*infra*), namely, by heating the concentrated aqueous solution of the latter with zinc-powder, assisting the action towards the end by gradual addition of hydrochloric acid till the zinc is completely dissolved. The reaction being completed, the liquid is neutralised with baryta-water, the zinc precipitated by barium sulphide, and the hydrochloric acid removed by repeatedly evaporating the solution, which when decolorised with animal charcoal and evaporated, leaves the phenomalic acid in the form of a colourless amorphous deliquescent mass. The same acid is formed by the action of more powerful reducing agents on trichlorophenomalic acid, but in that case it undergoes a further transformation into succinic acid and a body having the composition of acetic aldehyde, ($C^6H^{10}O^3 = C^4H^6O^4 + C^2H^4O$), which latter, however, is converted into an amorphous acid, or completely decomposed with separation of charcoal, according to the circumstances of the experiment.

Trichlorophenomalic Acid. $C^6H^3Cl^3O^3$ (Carius, *loc. cit.*).—Produced by the action of chlorous acid on benzene:

The best way of preparing it is to add potassium chlorate (150 grms.) by small portions to a mixture of benzene (80 grms.) and sulphuric acid (1200 grms.) diluted with half its weight of water, agitating after each addition, and cooling the vessel if necessary; then, after 3 or 5 days, heating the mixture to about 70° and adding sufficient warm water to prevent the potassium sulphate from crystallising out. The greater part of the trichlorophenomalic acid is then contained in the watery liquid (the rest in the brownish supernatant oil), and may be extracted by agitating with ether, evaporating the latter, dissolving the residue, consisting of trichlorophenomalic, sulphuric, and oxalic acids, in water, precipitating the sulphuric acid with barium chloride, and again treating with ether. From the viscid residue left on distilling off the ether, the trichlorophenomalic acid partly crystallises out, either in a vacuum or after heating for some hours to 40° – 50° , and a further portion separates after addition

of water sufficient to produce permanent turbidity. It is purified by recrystallisation from a quantity of hot water large enough to prevent it from separating as an oil on cooling.

Trichlorophenomalic acid crystallises in monoclinic forms, from the hot aqueous solution in laminae; by slow evaporation, or from other solvents, in tables or prisms with pyramidal faces. It melts at 131° – 132° , with partial volatilisation, but without decomposition, and solidifies on cooling to a crystalline mass of sp. gr. about 1.5; when slowly heated above its melting point, it is resolved, almost without residue, into water and white vapours of a new acid; when quickly heated to 180° , it decomposes, with strong intumescence and separation of charcoal. It dissolves sparingly in cold, easily in hot water, alcohol, ether, and warm benzol. The aqueous solution has an acid reaction, decomposes carbonates, gives white precipitates with silver and lead salts on cautious addition of ammonia, and does not prevent the precipitation of ferric salts by ammonia. It decomposes partially on exposure to light, assuming a reddish colour, very quickly on boiling, with formation of hydrochloric acid, and completely by heating with baryta-water, whereby it is converted into phenaconic acid, $C^6H^5O^6$ (p. 904). It does not appear to form a nitro-compound, but is decomposed by boiling with nitric acid, and more quickly by potassium chlorate and sulphuric acid, yielding oxalic acid; heated in solution with a small quantity of silver nitrate and ammonia, it throws down metallic silver. By nascent hydrogen it is reduced to phenaconic acid, and by stronger action to succinic acid; this last transformation is produced by heating the trichlorophenomalic acid to 160° – 180° in a sealed tube with saturated aqueous hydriodic acid; also by the action of tin and hydrochloric acid (Carius).

PHENYL or DIPHENYL. $C^{12}H^{10}$.—This hydrocarbon is formed, together with others, when benzene-vapour is passed through a red-hot tube: $2C^6H^4 = C^{12}H^{10} + H^2$; also, together with benzene, by passing chrysene-vapour mixed with hydrogen through a red-hot tube: $C^{18}H^{12} + 2H^2 = C^{12}H^{10} + C^6H^6$ (Berthelot, p. 459). Heated for an hour in a sealed tube filled with hydrogen it is partly resolved into benzene and chrysene, the latter being probably formed by polymerisation of phenylene produced in the first instance:

Passed together with ethylene through a red-hot tube, it is partly converted into cinnamene and benzene: $C^{12}H^{10} + C^2H^4 = C^8H^8 + C^6H^6$; partly into anthracene and hydrogen: $C^{12}H^{10} + C^2H^4 = C^{14}H^{10} + 2H^2$. Heated with 80 pts. of saturated hydriodic acid, it is almost wholly converted into hexane: $C^{12}H^{10} + 18HI = 2C^6H^{14} + 9I^2$; with 20 pts. of the acid, partly ($\frac{2}{3}$) into benzene: $C^{12}H^{10} + 2HI = 2C^6H^6 + I^2$; partly ($\frac{1}{3}$) into propane and carbon: $C^{12}H^{10} = C^3H^8 + C^9 + H^2$ (Berthelot, p. 741).

PHENYL CARBONATE. $CO^2(C^6H^5)^2$.—Obtained by heating 3 pts. phenol with 2 pts. liquid phosphene to 140° – 150° in a sealed tube. By heating the product with dilute soda-ley, a solid compound is obtained, which crystallises from hot alcohol in white needles having a silky lustre. It is insoluble in water, soluble in alcohol and ether, melts at 78° , gives off a pleasant aromatic odour when heated, and sublimes in long needles. By strong soda-ley, or more easily by alcoholic potash, it is resolved into carbonate and phenylate of sodium. Heated with strong sulphuric acid, it gives off carbon dioxide (Kemp, *Zeitschr. f. Chem.* [2] vi. 205).

PHENYL PHOSPHATES. According to Glutz (*Ann. Ch. Pharm.* cxliii. 181), the triphenylic phosphate, $PO^4(C^6H^5)^3$, obtained by treating phenol with phosphorus pentachloride, washing the residue with soda-ley and water, and dissolving in ether, crystallises from the latter by spontaneous evaporation as a coherent mass, consisting of transparent needles, snow-white and inodorous after drying over sulphuric acid. It melts at the heat of the water-bath, is insoluble in water, very easily soluble in alcohol, ether, and hot strong sulphuric acid, and crystallises from the latter in long needles having a silky lustre. By treatment with excess of potash or other strong bases, it is converted into diphenyl-phosphoric acid and phenol:

Diphenyl-phosphoric acid is separated from its potassium salt by hydrochloric acid, as a brown oil slightly soluble in water, easily in alcohol and ether. Its silver salt, $PO^4(C^6H^5)^2Ag$, crystallises in silky needles permanent in the air.

Triphenylic phosphate heated with bromine to 180° yields bromophenylic ortho-phosphate, which, after the crude product has been treated with dilute alkali, crystallises from hot alcohol in nacreous scales:

PHENYL SULPHYDRATE and SULPHIDES. *Phenyl sulphhydrate, Phenyl mercaptan, or Thiophenol*, C^6H^5SH , was first obtained by Vogt (iv. 418) by the action of nascent hydrogen on sulphophenyl chloride: he describes it as a colourless, strongly refracting, oily liquid, having an intensely disagreeable odour and boiling at 165° (iv. 418). Stenhouse (*Proc. Roy. Soc.* xvii. 62) has obtained it in greater purity by distilling sodium phenylsulphite in an iron retort (it suffers decomposition in copper retorts): it then passes over between 165° and 180° , and is obtained by rectification as a strongly refracting liquid, having an aromatic, somewhat allineous, but by no means unpleasant odour, and boiling at 172.5° . The portion of the crude distillate passing over between 290° and 300° yields a large quantity of pure phenyl sulphide, $(C^6H^5)_2S$. Otto (*Ann. Ch. Pharm.* cxliii. 211) obtained phenyl mercaptan by the action of nascent hydrogen on sulphophenylene-ethylene, $\left. \begin{matrix} C^6H^5SO^2 \\ C^6H^5 \end{matrix} \right\}$, and found it to boil between 170° and 173° .

Phenyl mercaptan is likewise obtained, together with the monosulphide, by the action of phosphorus pentasulphide on phenol. The sulphhydrate, which is the chief product, distils over first (together with phenol and benzene); afterwards, towards 290° , a considerable quantity of liquid passes over, from which, by rectification, pure phenyl sulphide, $(C^6H^5)_2S$, may be obtained: this latter compound appears to be formed by decomposition of the phenyl sulphophosphate occurring in the less volatile portions of the product. Phenylsulphide is likewise obtained, together with a residue of lead sulphide, by the dry distillation of the lead salt of phenyl mercaptan, $(C^6H^5)_2Pb = (C^6H^5)_2S + PbS$. The compound $C^{12}H^{10}SO^2$, produced by oxidation of phenyl sulphide, and designated by Stenhouse as *sulphobenzolene* (v. 489), is identical with sulphobenzene or sulphobenzide (v. 486), produced by the action of sulphuric anhydride on benzene (Kekulé & Szech, *Zeitschr. f. Chem.* [2] iii. 193, 306; *Jahresb.* 1867, p. 628).

Phenyl Bisulphide, $(C^6H^5)_2S^2$, is produced by oxidation of the sulphhydrate: $2C^6H^5S + O = H^2O + (C^6H^5)_2S^2$ (iv. 417); also by heating the mercury-compound of the sulphhydrate in the dry state above its melting point, or with water in a sealed tube to 180° : $(C^6H^5)_2S^2Hg = Hg + (C^6H^5)_2S^2$ (Dreher & Otto, *Zeitschr. f. Chem.* [2] vi. 22). It melts according to Stenhouse at 61° , according to Vogt at 60° ; is insoluble in water, soluble in alcohol, very soluble in ether, benzol, and carbon bisulphide (Stenhouse). It combines directly with bromine, forming the compound $C^{12}H^{10}S^2Br^2$, which crystallises in nacreous laminae, insoluble in water, easily soluble in ether, less soluble in alcohol, volatile without decomposition (Wheeler, *Zeitschr. f. Chem.* [2] iii. 436).

Chlorophenyl Sulphhydrate, C^6H^5ClSH , is formed by bringing sulphochlorobenzene chloride in contact with zinc and dilute sulphuric acid:

It volatilises when distilled with aqueous vapour, and crystallises from alcohol in large, soft, four-sided rhombic tables, having a highly offensive odour; melts at 53° – 54° , volatilises undecomposed when slowly heated, is insoluble in water, but dissolves easily in ether, benzol, and hot alcohol. Its lead compound, $(C^6H^5ClS)_2Pb$, is a lemon-yellow precipitate insoluble in water and in alcohol. *Chlorophenyl Bisulphide*, $(C^6H^5ClS)_2$, produced by heating the sulphhydrate with nitric acid of sp. gr. 1.12, crystallises from alcohol in large six-sided tables, inodorous, melting at 71° , distilling without decomposition, insoluble in water, soluble in ether and in hot alcohol. In contact with zinc and sulphuric acid, it is reconverted into chlorophenyl sulphhydrate (Glutz, *Ann. Ch. Pharm.* cxliii. 181; *Jahresb.* 1867, p. 632).

Phenyl Oxyulphide or Diphenyl-dioxyulphide, $C^{12}H^{10}SO^2$, is produced, together with phenylsulphurous or sulphobenzolic acid, when phenylsulphurous hydride is heated with water to 130° :

The oxyulphide, which separates as a crystalline mass from the aqueous solution of phenylsulphurous acid, is insoluble in water and alkalis, easily soluble in ether, hot benzol, and alcohol, and crystallises in long four-sided needles which melt at 36° . In contact with zinc and sulphuric acid it is easily converted into phenyl sulphhydrate:

By the action of bromine in presence of water, it is converted into *monobromodiphenyl oxyulphide*, $C^{12}H^9BrSO^2$, a viscid yellowish liquid insoluble in water, easily soluble in benzol and ether, converted by hot strong aqueous ammonia into sulphobenzolamide and phenyl-bisulphide:

Chlorophenyl Oxysulphide, $C^6H^5Cl^2S^2O^2$, is produced, like phenyl oxysulphide, by heating chlorophenylsulphurous hydride with water to 130° – 140° :

It is insoluble in water and alkalis, easily soluble in ether, benzol, and hot alcohol; crystallises from the latter in vitreous four-sided rhombic prisms; melts at 136° – 138° ; dissolves with indigo colour in fuming sulphuric acid, and is converted by zinc and sulphuric acid into chlorophenyl sulphhydrate (Otto, *Ann. Ch. Pharm.* cxiv. 317; *Jahresb.* 1867, p. 629).

PHENYL-ACETYLENE. Syn. with ACETENYL-BENZENE (p. 5).

PHENYLACRYLIC ACID. Syn. with CINNAMIC ACID (p. 467).

PHENYLAMINE or **ANILINE**. $C^6H^5NH^2$.—On the preparation of this base on the manufacturing scale, and on the manufacture and properties of aniline colours, see the article ANILINE in this volume.

Reactions.—1. Aniline treated in very dilute solution with *potassium permanganate* is oxidised to hydrazobenzene, $C^6H^5N^2$, azobenzene, $C^6H^5ON^2$, and azoxybenzene, $C^6H^5ON^2O$ (Glaser, pp. 269–272).—2. Heated with 20 pts. of saturated aqueous *hydriodic acid*, it yields ammonia and benzene; methylaniline similarly treated yields methane and hexane, together with ammonia; ethylaniline yields ethane and hexane; amylaniline yields quintane and hexane (Berthelot).—3. When a dilute aqueous solution of an aniline salt is mixed with *iodine chloride* containing a slight excess of iodine, two oxidised compounds are formed, one soluble in carbon bisulphide, and forming shining crystals several inches long, while the other, which is formed in smaller quantity, is insoluble in carbon bisulphide, and crystallises in reddish scales (Stenhouse, *Chem. Soc. J.* [2] ii. 327).

4. Aniline well cooled and added by drops to *phosphorus trichloride*, is converted into the hydrochloride of phosphaniline, $C^6H^5PN^2 \cdot 3HCl$ (Tait, *Zeitschr. f. Chem.* [2] 648). (See PHOSPHANILINE, p. 932).—5. When 3 pts. aniline are heated to 145° with 1 pt. *chloropicrin*, nitrogen is abundantly evolved, and the residue yields to water a red colouring matter, together with hydrochloride of carbobisphenyltri-amine, $C^6(C^6H^5)^3H^2N^3$ (Basset, *Chem. Soc. J.* [2] iii. 21).—6. A mixture of 2 mol. aniline and 1 mol. *chlorotoluene* heated to 160° for 24 hours yields aniline hydrochloride, together with a base isomeric with phenyl-tolylamine (Fleischer, *Ann. Ch. Pharm.* cxxxviii. 225):

7. Aniline in excess heated with *ethyl monochloracetate* and water in a sealed tube to 130° – 140° , is converted into anilido-acetanilide, together with alcohol and aniline hydrochloride (Wilm a. Wischin, *Zeitschr. f. Chem.* [2] iv. 75):

8. On the action of *glycolic chlorhydrin* on aniline, see Wurtz (*Zeitschr. f. Chem.* [2] v. 482).—9. Aniline heated with *hydrochloric acid* and *potassium ferrocyanide* is converted into a red colouring matter called *lydine* (Guyot, p. 793).

10. Aniline unites with *sulphurous oxide* (as described by Hofmann), apparently forming the compound $C^6H^5N \cdot SO^2$, or perhaps $(SO^2)^N_{H^2}O$, which when exposed to

the air gives off a large quantity of sulphurous oxide, leaving the compound $2C^6H^5N \cdot SO^2$; and this when suspended in ether, again takes up sulphurous oxide. *Acetic aldehyde* acts violently on the compound $C^6H^5N \cdot SO^2$, forming a brown viscid mass chiefly consisting of diethyldene-diphenylamine. In ethereal solution colourless prisms are formed, consisting of $C^6H^5N \cdot C^2H^5O \cdot SO^2$, insoluble in ether, slightly soluble in cold water, easily in alcohol, and decomposed by heat, with formation of *diethyldene-diphenyl-diamine* (iv. 457), which is easily prepared in this manner:

Ænanthol and *bitter almond oil* act less energetically, forming the compounds

$2\text{C}^6\text{H}^4\text{N} \cdot 2\text{C}^6\text{H}^4\text{O} \cdot \text{SO}^2$ and $2\text{C}^6\text{H}^4\text{N} \cdot 2\text{C}^6\text{H}^4\text{O} \cdot \text{SO}^2$. The more easily decomposable valeral compound seems to have a similar constitution (Schiff, *Ann. Ch. Pharm.* cxi. 92).

11. On the action of aldehydes on aniline, see DIPHENYLDIAMINES (iv. 456, and p. 79 of this volume).

12. On the action of the camphene hydrochlorides, $\text{C}^6\text{H}^{14} \cdot \text{HCl}$ and $\text{C}^6\text{H}^{14} \cdot 2\text{HCl}$, on aniline, see TEREBENES.

Bromophenylamines.—Mono- and di-bromaniline are formed, as well as tri-bromaniline, by the direct action of bromine on aniline, namely, by passing bromine-vapour mixed with air into aniline, or by gradually adding a solution of bromine in benzol to aniline also dissolved in benzol (Kekulé, *Zeitschr. f. Chem.* [2] ii. 667). Di- and tri-bromaniline are also produced by heating nitrobenzene to 185° – 190° in sealed tubes with fuming hydrobromic acid, the nitrobenzene being first reduced to aniline, according to the equation :

and the free bromine then acting upon the aniline as above (Baumhauer, *Zeitschr. f. Chem.* [2] v. 198).

Trichloraniline, $\text{C}^6\text{H}^3\text{Cl}^3\text{N}$, is formed by the action of tin and hydrochloric acid on trichloronitrobenzene in alcoholic solution: $\text{C}^6\text{H}^2\text{Cl}^3(\text{NO}^2) + 3\text{H}^2 = 2\text{H}^2\text{O} + \text{C}^6\text{H}^3\text{Cl}^3\text{N}$. By dissolving the crystalline compound which separates on cooling in alcohol, freeing it from tin by hydrogen sulphide, and evaporating the filtrate, trichloraniline is obtained in long shining needles slightly soluble in cold, more soluble in hot water, also in alcohol, ether, benzol, moderately dilute mineral acids, and strong caustic potash. With strong sulphuric acid it forms a rose-coloured solution, from which the trichloraniline may be distilled without alteration. It melts at 96.5° , solidifies at 86° , and boils near 270° . The aqueous solution forms with chloride of lime or chromic acid a dye of the colour of vermilion. The solution in strong sulphuric acid becomes bluish-violet on addition of a little nitric acid, and then reddish-yellow when warmed or mixed with water. The vapour passed over red-hot lime yields ammonia and aniline (Lesimple, *Ann. Ch. Pharm.* cxxxvii. 125).

Iodaniline, $\text{C}^6\text{H}^4\text{IN}$, exhibits two modifications, α and β , obtained from the corresponding modifications of diazonitrobenzene :

An aqueous solution of α diazonitrobenzene nitrate mixed with hydriodic acid yields α iodonitrobenzene, crystallising in yellow needles, melting at 171.5° , and identical with that which is obtained by the action of nitric acid on iodobenzene, and this compound treated with ammonium sulphide is converted into α iodaniline melting at 60° , and identical with that which Hofmann obtained by the action of iodine on aniline (iv. 444). β Iodonitrobenzene, obtained in like manner from β diazonitrobenzene, is converted by ammonium sulphide into β iodaniline or para-iodaniline, crystallising in silvery laminae, and melting at 25° .

The melting points of α iodaniline and of all the benzene-derivatives of the same series are higher than those of the corresponding compounds of the β or para- series ; thus :

	α	β
Iodonitrobenzene	171.5°	34°
Bromonitrobenzene	120°	56°
Chloronitrobenzene	83°	46°
Nitraniline *	141°	108°
Iodaniline	60°	26°
Bromaniline	57°	liquid at ord. temp.
Chloraniline	64°	
Diazo-amidonitrobenzene	245°	195°
Diazo-nitrobenzolimide	71°	53°

(Griess, *Chem. Soc. J.* [2] v. 857; *Jahresb.* 1866, p. 457).

* The prefixes α and β are here applied to the nitranilines in the opposite sense to that attached to them in vol. iv. p. 446, β or para-nitraniline being the modification obtained by reduction of dinitrobenzene.

***β* Nitraniline** treated in alcoholic solution with sodium-amalgam is converted into hydrazoaniline, $C^6H^3N^4$ (Harrhaus, p. 703).

Diphenylamine. $(C^6H^5)_2HN$.—This base, discovered by Hofmann (iv. 453) amongst the products of the dry distillation of aniline-blue, is likewise formed by the action of aniline on various aniline salts, according to the equation: $C^6H^5 \cdot H^2N + C^6H^5 \cdot H^2N = (C^6H^5)_2HN + NH_3$. It may be prepared by heating 1½ mol. aniline with 1 mol. aniline hydrochloride to 210° – 214° for thirty to thirty-five hours in a long-necked flask provided with a condensing tube, or more quickly by heating the same mixture in a closed vessel under a pressure of four or five atmospheres. On treating the product—which is a mixture of diphenylamine hydrochloride, aniline hydrochloride, and colouring matters—with hot hydrochloric acid diluted with 20 to 30 times its bulk of water, the diphenylamine hydrochloride is decomposed by the water, and the base thus separated rises to the surface as an oil which solidifies on cooling: it is purified by repeated crystallisation from ether or benzol, in which the colouring matters are insoluble, and finally by distillation. It then forms a white substance which boils at 310° (De Laire, Girard, a. Chapoteant, *Bull. Soc. Chim.* [2] vii. 360).

Phenyl-diamines (Hofmann, *Proc. Roy. Soc.* xv. 55).—Diamines containing 2 atoms of phenyl and 1 atom of a trivalent alcohol-radicle, such as methenyl, ethenyl, &c., are produced by the action of phosphorus trichloride on a mixture of aniline with a fatty acid, acid chloride, or anilide, e.g. ethenyl-diphenyl-diamine, $(C^6H^5)_2(C^2H^3)HN^2$, by the action of PCl_3 on a mixture of aniline with acetic acid, acetyl chloride, or phenyl-acetamide. The phenyl-diamines containing ethenyl are described under **ETHENYL-DIAMINES** (p. 685). *Methenyl-diphenyl-diamine*, $(CH)(C^6H^5)_2HN^2$, is described as formyl-diphenyl-diamine in vol. iv. p. 459.

Quintenzyl-diphenyl-diamine, $C^{17}H^{20}N^2 = \left\{ \begin{smallmatrix} (C^6H^5)'' \\ (C^6H^5)^2 \\ H \end{smallmatrix} \right\} N^2$, is obtained by heating 3 mol.

valeric acid and 6 mol. aniline with 2 mol. phosphorus trichloride to 150° , precipitating the aqueous solution of the resulting viscid mass with soda-ley, and recrystallising from alcohol. It is nearly insoluble in water, melts at 111° , and forms a platinum salt which crystallises in rhombic tables, slightly soluble in water, nearly insoluble in alcohol.

Benzenzyl-diphenyl-diamine, $C^{10}H^{16}N^2 = \left\{ \begin{smallmatrix} (C^6H^5)'' \\ (C^6H^5)^2 \\ H \end{smallmatrix} \right\} N^2$, obtained in like manner with

3 mol. phenyl-benzamide, 3 mol. aniline hydrochloride, and 1 mol. phosphorus trichloride, crystallises in slender silky needles; the hydrochloride in sparingly soluble laminae, which lose the whole of their acid on recrystallisation.

Phenyl-diamines containing aldehyde-radicles, ethylidene, benzylidene, &c., produced by the action of aldehydes on aniline, have been obtained by Schiff, and several of them are described in vol. iv. pp. 456–459.

Ethylidene-diethyl-diphenyl-diamine, $C^{18}H^{24}N^2 = (C^2H^4)(C^6H^5)_2(C^6H^5)_2N^2$, produced by the action of acetic aldehyde on ethyl-aniline, is a thick, bitter, scentless liquid, not distillable without decomposition, and forming with the stronger acids, salts which are decomposed by water. The *platinochloride* has the composition $2(C^{18}H^{24}N^2 \cdot HCl) \cdot PtCl_4$.

Diethylidene-diphenyl-diamine, $(C^2H^4)^2(C^6H^5)_2N^2$, previously obtained by the action of enanthol on aniline, is also produced by heating aniline with enanthol-sodium sulphite:

The dibenzylidene compound is obtained in a similar manner (Schiff, *Ann. Ch. Pharm.* cxl. 92; *Jahresb.* 1866, p. 440).

PHENYLENE SULPHIDE (Stenhouse, *Proc. Roy. Soc.* xvii. 62; *Ann. Ch. Pharm.* cxlix. 252).—This compound is produced, together with phenylic sulphate and monosulphide, by the dry distillation of sodium phenylsulphite in an iron vessel, and remains after all the products volatile at 300° have passed over. On distilling the dark-coloured residue in a copper retort, an orange-coloured distillate is obtained, which after several days deposits a considerable quantity of large tabular crystals; and these, when freed from adhering oil by draining and pressure between paper, from phenyl bisulphide and other impurities by exhaustion with hot alcohol, and recrystallised from benzol or carbon bisulphide, and finally from alcohol, yield pure phenylene sulphide, in long, colourless, transparent, shining prisms. It is insoluble in water, slightly soluble in cold alcohol (1 pt. in about 400), more soluble in hot

alcohol; melts at 159° , and resolidifies at 153° . It dissolves in strong sulphuric acid, forming a liquid of a splendid purple colour, and becoming red with a purple tinge when mixed with a considerable quantity of the concentrated acid; on addition of water this colour disappears, and a crystalline precipitate separates, which appears to consist of unaltered phenylene sulphide. With strong nitric acid it yields a crystalline substance, probably a nitro-substitution product.

PHENYLENE SULPHOBROMIDE, $C^6H^4SBr^2$, is produced by the action of bromine-vapour on phenylene sulphide, or more easily by adding bromine in slight excess to a cold-saturated solution of the sulphide in anhydrous carbon bisulphide, the compound then separating in small black prisms, which may be purified by washing with cold carbon bisulphide, and freed from that liquid by placing them under an air-pump receiver, exhausting, readmitting the air, and repeating these operations several times. The sulphobromide slowly gives up its bromine when exposed to dry air, and is quickly decomposed by moisture, with evolution of hydrobromic acid. It is moderately soluble in carbon bisulphide and in carbon tetrachloride (Stenhouse, *loc. cit.*).

PHENYLENE-DIAMINE. $C^6H^4N^2 = \begin{matrix} (C^6H^4) \\ | \\ H^2 \end{matrix} N^2$ (iv. 480).—The hydrides of α and β phenylene-diamine are formed by the action of hydriodic acid on the corresponding nitranilines, the reduction of the α nitraniline appearing to require a somewhat higher temperature than that of β nitraniline. The α hydriodide is easily soluble, and crystallises in indistinct laminae; the β salt is but slightly soluble, and crystallises in broad micaceous rectangular tables (Mills, *Chem. Soc. J.* [2] ii. 152).

Beta- or para-phenylene-diamine is formed, together with aniline, by heating amidazobenzene with tin and hydrochloric acid (Martius a. Griess, *Jahresb.* 1865, p. 419):

A double salt of phenylene-diamine hydrochloride and stannous chloride, $C^6H^4N^2 \cdot 2HCl \cdot 2SnCl^2$, is formed by treating a mixture of dinitrobenzene (1 mol.) and metallic tin (6 at.) with strong hydrochloric acid. The whole dissolves with violent action, and the solution when left to evaporate deposits the double salt in needles having a silky lustre (H. Gerdemann, *Zeitschr. f. Chem.* [2] i. 51).

When nitrous acid is passed into the aqueous solution of phenylene-diamine hydrochloride, nitrogen is evolved, and a dark violet body, $C^2H^4N^2O^2$, is formed, slightly soluble in water, alcohol, and ether. This body slowly gives off nitrogen when treated with hydrochloric acid, and yields aniline hydrochloride when boiled with tin and hydrochloric acid. An acidulated solution of phenylene-diamine hydrochloride gives with potassium nitrite a brown amorphous precipitate (Hollemann, *ibid.* 555).

Dibromophenylene-diamine, $C^6H^4Br^2N^2$, is obtained as a dark brown precipitate on mixing the hydrochloride of phenylene-diamine with bromine till the odour of the latter remains permanent after some hours. It is nearly insoluble in ether, but dissolves easily in alcohol, and crystallises therefrom; cannot be sublimed without decomposition (Hollemann).

PHENYL-HYPOSULPHUROUS ACID. $C^6H^4S^2O^3$ (Stenhouse, *Proc. Roy. Soc.* xvii. 62; *Ann. Ch. Pharm.* cxlix. 254).—This acid is formed by dissolving phenyl sulphide $(C^6H^5)^2S$, with aid of heat in strong sulphuric acid. On dissolving the semi-solid mass which forms on cooling in a large quantity of water, neutralising with barium carbonate, evaporating the filtrate till a crystalline film forms on its surface, and then leaving it to cool, *barium phenylhyposulphite*, $(C^6H^5S^2O^3)^2Ba + 2H^2O$, separates in crusts composed of microscopic crystals. The copper salt also forms crystalline crusts. The calcium and sodium salts do not crystallise so well as the barium salt.

PHENYL-SULPHURIC ACID. $C^6H^4SO^4$ (Kekulé, *Zeitschr. f. Chem.* [2] iii. 641; *Jahresb.* 1867, p. 637).—Two modifications of this acid, which may be distinguished as α and β , are produced by dissolving phenol at a gentle heat in an equal weight of strong sulphuric acid; on diluting the product with water, neutralising with lead carbonate, decomposing the lead salts with hydrogen sulphide, neutralising the acid filtrate with potassium carbonate, and evaporating, potassium α phenylsulphate crystallises out first in six-sided anhydrous laminae, while the β phenylsulphate is obtained from the mother-liquor in needles containing 2 mol. water. These two potassium salts, when fused with excess of potash, yield different modifications of oxyphenol, $C^6H^3O^2$, the α salt yielding resorcin, and the β salt pyrocatechin:

From this it would appear that the α and β phenylsulphuric acids both have the constitution $C^6H^5\left\{\begin{smallmatrix} OH \\ SO^3H \end{smallmatrix}\right.$, and differ only in the relative positions of the radicles OH and SO^3H ; in fact, that the α acid is paraphenylsulphuric acid (1, 4), and the β acid metaphenylsulphuric acid (1, 3). But from the different reactions of the α and β potassium salts with benzoyl chloride (p. 925), the two acids appear rather to be related to one another in the same manner as isethionic and ethylsulphuric acids; thus:

A third modification, γ phenylsulphuric acid, has been shown by Solommanoff (*Zeitschr. f. Chem.* [2] v. 294) to be formed, simultaneously with the α and β acids, by the action of sulphuric acid on phenol, its potassium salt being obtained in small quantity from the last mother-liquors of the β potassium salt.

α Phenylsulphate of potassium melts at 240° and decomposes at a higher temperature. Its aqueous solution gives with basic lead acetate a white precipitate of a basic lead salt nearly insoluble in boiling water. Potassium β phenylsulphate crystallises with various quantities of water; from boiling water it separates with 1 mol. water; by spontaneous evaporation, with 2 mol. It is efflorescent, and is sharply distinguished from the α and γ salts by its property of melting at 235° – 240° to a yellow transparent liquid which solidifies to a vitreous mass on cooling. Its aqueous solution gives with basic lead acetate a white precipitate of a basic β phenylsulphate of lead, which cakes together when the liquid is boiled, is dissolved by boiling water, and separates out as a white powder on cooling. The γ potassium salt crystallises in thin plates and needles, and is very soluble in water; the crystals contain about $2\frac{1}{2}$ mol. water, and do not effloresce quite so quickly as those of the β salt; they do not melt at 240° . With basic lead acetate this salt gives a white precipitate which does not cake together on heating the liquid, and is but slightly dissolved by boiling water (Solommanoff).

The α potassium salt is obtained at once in the pure state by digesting 1 mol. phenol at a gentle heat with 1 mol. chlorhydric sulphate, SO^3HCl , neutralising the aqueous solution of the product with barium carbonate, and decomposing the resulting barium salt with potassium carbonate. When 1 mol. SO^3HCl is digested with 2 mol. phenol, and the aqueous solution of the product is agitated with ether to remove unaltered phenol, then neutralised with potassium carbonate and evaporated, the solution first deposits laminae of the α potassium salt, and the mother-liquor yields needles of the β salt. The dry α potassium salt treated with chlorhydric sulphate is converted into potassium phenyl-disulphate, $C^6H^5OH(SO^3K)^2$ (Solommanoff).

Several salts of phenylsulphuric acid (α ?) have been examined by Menzner (*Ann. Ch. Pharm.* cxliii. 75; *Jahresb.* 1867, p. 641).

Chlorophenyl-sulphuric acid, $C^6H^5Cl.SO^3H$, is formed by mixing 200 grms. monochlorophenol with 150 grms. fuming sulphuric acid. On leaving the crystallising mass to itself for some days, then converting it into a barium salt, and the latter into a potassium salt, the anhydrous salt $C^6H^5Cl.SO^3K$ separated out first in stellate groups of short flat prisms; then the hydrated salt $C^6H^5Cl.SO^3K + 2H^2O$, in flat colourless monoclinic crystals, often united in crosses. This salt gives off its water at 110° , melts at 245° , and decomposes with intumescence at 300° . The mother-liquor contained considerable quantities of very soluble salts (Bähr-Predari, *Zeitschr. f. Chem.* [2] vi. 246).

Dichlorophenylsulphuric acid, $C^6H^4Cl^2.SO^3H$, is produced as a potassium salt by stirring up a mixture of 10 pts. of potassium phenylsulphate (α) and 3 pts. potassium chlorate with 22 pts. commercial hydrochloric acid, the mixture being cooled, if necessary, to moderate the action. The resulting pasty mass washed with alcohol and ether to remove chlorophenols, and recrystallised from hot water, yields the potassium salt, $C^6H^4Cl^2.SO^3K$, in white shining scales, easily soluble in hot, less soluble in cold water. The acid $C^6H^4Cl^2.SO^3H$, prepared by decomposing this salt with an equivalent quantity of dilute sulphuric acid, evaporating to dryness, exhausting the residue with absolute alcohol, and evaporating the alcoholic solution, finally in a vacuum over sulphuric acid, crystallises in colourless very deliquescent rhombic tables or prisms. The barium salt, $C^6H^4Cl^2.SO^3Ba + 2H^2O$ (at 100°), separates by

evaporation in white crystalline crusts (Kolbe & Gauhe, *Ann. Ch. Pharm.* cxlvii. 71; *Zeitschr. f. Chem.* [2] v. 232).

On the chlorophenylsulphuric acids, see, further, Petersen a. Bähr-Prodari (*Ann. Ch. Pharm.* [1871] cxlvii. 121-165; *Chem. Soc. J.* [2] ix. 240).

Nitrophenylsulphuric Acid. $C^6H^4(NO^2)SO^2H$.—The potassium salt of this acid is obtained by heating a mixture of 1 pt. finely pulverised potassium phenol-sulphate (a) and 1 pt. nitre with 1 pt. strong sulphuric acid and 5 pts. water, and purified in the same manner as the dichlorophenylsulphate. When decomposed by dilute sulphuric acid, it yields nitrophenolsulphuric acid, which crystallises from alcohol by evaporation, finally in a vacuum, in colourless, short, whetstone-shaped, very deliquescent crystals. Ammonium sulphide converts it into a difficultly crystallisable substance, probably the corresponding amido-acid.

Nitrophenylsulphuric acid forms salts containing 1 and 2 at. metal. The *potassium salt*, $C^6H^4(NO^2)SO^2K$, crystallises in stellate groups of needles; the *ammonium salt*, $C^6H^4(NO^2)SO^2(NH^4)^2$, in brownish-yellow prisms. The *barium salt*, $C^6H^4(NO^2)SO^2Ba$, forms small indistinct orange-red crystals, which retain 2 mol. crystallisation-water at 100° , and become anhydrous at 170° – 180° . The *cuprie salt*, $[C^6H^4(NO^2)SO^2]^2Cu$, is a yellow-green indistinctly crystalline mass. The *lead salt*, $[C^6H^4(NO^2)SO^2]^2Pb$, crystallises in short thick yellow needles, easily becoming basic by evaporation (Kolbe & Gauhe).

Kekulé (*Zeitschr. f. Chem.* [2] v. 602) has obtained the same acid by the action of sulphuric acid on the volatile modification of nitrophenol.

Benzoyl-phenylsulphuric Acid. $C^6H^4(C^6H^5O)SO^2H = C^6H^4\{SO^2H \atop OC^6H^5O\}$ (Engelhardt & Latschinoff, *Zeitschr. f. Chem.* [2] iv. 75).—This acid is produced: 1. As a potassium salt by heating the potassium salt of a phenylsulphuric acid with benzoyl chloride for some hours to 140° – 150° . The chlorine then acts on the hydrogen of the water-residue in the phenol, forming hydrochloric acid, and the benzoyl takes the place of the hydrogen removed; thus:

The dry white residue washed with ether to remove admixed benzoyl chloride and benzoic acid, and recrystallised from boiling water, yields needle-shaped crystals of potassium benzoyl-phenylsulphate.

2. By treating 1 mol. phenyl-sulphuric acid (formed from C^6H^5O and SO^2H^2) with 2 mol. benzoyl chloride. The reaction is as follows:

The reaction is assisted by a gentle heat; and the product is treated with cold water, which extracts the benzoyl-phenylsulphuric acid, and leaves benzoic acid, phenyl benzoate, and an indifferent oil resulting from the action of the benzoyl chloride on the β phenylsulphuric acid present. On saturating the aqueous solution with barium carbonate, the sparingly soluble benzoyl-phenylsulphate of barium is deposited, while an easily soluble not isomeric salt remains in the mother-liquor.

3. By the action of sulphuric anhydride on phenyl benzoate cooled with snow:

The quantity of benzoyl-phenylsulphuric acid obtained by this method is however but small, and another acid not yet examined is formed at the same time.

The acid obtained by the second or third process yields a potassium salt exactly agreeing with that obtained by the first process. This acid may therefore be distinguished as a benzoyl-phenylsulphuric acid. Its formation in the second process results from the action of the benzoyl chloride on the α phenylsulphuric acid present, the β acid giving rise to the indifferent oil above mentioned.

Potassium a Benzoyl-phenylsulphate, $C^6H^4(OC^6H^5O)SO^2K$, dissolves easily in boiling, sparingly in cold water, and separates from aqueous solution in long needles; it dissolves also in boiling alcohol, and separates therefrom in flat shining needles. Heated with hydrochloric acid, it decomposes, with separation of benzoic acid; a similar decomposition takes place also when it is digested with potassium carbonate.

The *barium salt*, $[C^6H^4(OC^6H^5O)SO^2]^2Ba$, precipitated from the solution of the potassium salt by barium chloride, is sparingly soluble in cold, nearly insoluble in boiling water, and separates from the hot solution on cooling in tufts of slender needles. The *calcium salt*, $[C^6H^4(OC^6H^5O)SO^2]^2Ca$, resembles the barium salt. The

lead salt, $[C^6H^4(OC^2H^5O)SO^3]^2Pb + 2H^2O$, dissolves sparingly in cold, more easily in boiling water, and crystallises in nodular tufts of needles. The **magnesium salt** crystallises in shining laminae slightly soluble in cold, more easily in boiling water. The **copper salt**, $[C^6H^4(OC^2H^5O)SO^3]^2Cu + 6H^2O$, forms shining blue laminae, which give off water and become colourless when heated. The **silver salt**, $C^6H^4(OC^2H^5O)SO^3Ag$, crystallises in laminae more soluble in hot than in cold water.

Benzoyl chloride acts upon the potassium salt of γ phenyl-sulphuric acid at 140° , in the same manner as on the α salt, producing potassium γ benzoyl-phenylsulphate, which when dried at 130° has the composition $C^6H^4(OC^7H^5O)SO^3K$. It is sparingly soluble in cold, easily in boiling water, and separates as a gelatinous mass consisting of nodular groups of very slender needles. It dissolves also in boiling alcohol, and the solution solidifies on cooling to a gelatinous mass changing spontaneously to stellate groups of needles. The **barium salt**, $[C^6H^4(OC^2H^5O)SO^3]^2Ba$, is less soluble in water than the corresponding α salt, and separates from a boiling solution on cooling, in the form of a white powder (Solomonoff, *Zeitschr. f. Chem.* [2] v. 297).

The potassium salt of β phenylsulphuric acid reacts with benzoyl chloride quite differently from the α and γ salts. The mixture heated to 125° melts, without evolution of hydrochloric acid, to a yellow liquid, which solidifies on cooling to a viscid amorphous mass; and on treating this mass with potash, dissolving the oil thereby separated in ether, and evaporating, a crystalline mass is obtained which, when freed by pressure from a yellow oil and redissolved in alcohol and ether, yields crystals of phenyl-benzoyl or benzophenone, $C^6H^5 \cdot C^6H^5O$. This is the only well-characterised product of the reaction. The yellow oil has not been analysed, but it appears to contain sulphur. Only a very small quantity of potassium benzoyl-phenyl-sulphate is obtained, consisting apparently of the γ modification, the formation of which is due to the presence of a small quantity of γ phenyl-sulphate (Solomonoff).

From the reactions above detailed it appears that α and β phenylsulphuric acids are related to one another in the same manner as isethionic and ethyl-sulphuric acids, the α acid being constituted like isethionic acid, $C^2H^4 \begin{Bmatrix} SO^3H \\ OH \end{Bmatrix}$, and ethyl-sulphuric

acid, $O \begin{Bmatrix} C^2H^4 \\ SO^3H \end{Bmatrix}$

The relation of these acids to phenol may be exhibited by the following formulæ:

Phenol,	C^6H^5OH .
Potassium phenate,	C^6H^5OK .
Phenyl benzoate,	$C^6H^5O(C^7H^5O)$.
α Phenyl-sulphuric acid,	$C^6H^4(SO^3H)OH$.
Benzoyl-phenylsulphuric acid,	$C^6H^4(SO^3H)O(C^7H^5O)$.
β Phenylsulphuric acid,	$C^6H^4O(SO^3H)$.
Phenyl-phosphoric acid,	$C^6H^5O(PO^3H^2)$.

The formula of β phenyl-sulphuric acid, which contains no alcoholic hydrogen, shows that this acid cannot give rise to an isomeride of the benzoyl-phenylsulphuric acid derived from α phenylsulphuric acid (Engelhardt a. Latschinoff). As α and γ phenylsulphuric acids both give rise to benzoyl-phenylsulphuric acids, they probably differ only in the relative positions of the groups OH and SO^3H .

Phenyl-disulphuric Acid. $C^6H^4S^2O_7 = C^6H^4 \begin{Bmatrix} SO^3H \\ SO^3H \\ OH \end{Bmatrix}$ (Kekulé, *Zeitschr. f.*

Chem. [2] ii. 693. Engelhardt a. Latschinoff, *ibid.* iv. 270). **Disulphophenylenic Acid** (Griess, *Jahresb.* 1866, p. 466). **Oxyphenylene-disulphonic Acid** (Weinhold, *Ann. Ch. Pharm.* cxliii. 58). **Phenyl-disulphonic Acid** (Städeler, *ibid.* cxliv. 295).—This acid is produced by treating phenylsulphuric acid or phenol with excess of ordinary strong sulphuric acid, or better with a mixture of ordinary and fuming sulphuric acid, or with vapour of sulphuric anhydride, also by the action of strong sulphuric acid on diazobenzene sulphate. Engelhardt a. Latschinoff heat 100 grms. phenol on the water-bath with 400 grms. of a mixture of equal parts of ordinary and fuming sulphuric acid. On diluting the product with water, nearly saturating it with barium carbonate, and concentrating the slightly acid filtrate, an abundant crystallisation of barium phenyldisulphate is obtained, which may be purified by recrystallisation from water.

Phenyl-disulphuric acid separated from its lead or barium salt, and evaporated over sulphuric acid, crystallises at first in long silky needles, and then solidifies to a very deliquescent crystalline mass (Städeler). According to Weinhold, the solution

evaporated to a syrup solidifies after some time in stellate groups of silky crystals, which are very deliquescent, dissolve readily in alcohol, melt when heated, and decompose above 100° , with formation of sulphuric acid and emission of an odour of phenol.

The metallic phenyldisulphates, with exception of the basic lead salt, are very soluble, and crystallise with difficulty; they do not decompose when heated to 180° with potash-ley, but yield sulphuric acid when treated with nitric acid, chlorine, potassium chlorate and hydrochloric acid, or with hydriodic acid. The *potassium salt*, $2C^6H^4S^2O^4K^2 + H^2O$, crystallises in monoclinic prisms which give up their water when heated above 100° . The *dibasic salt*, $C^6H^4S^2O^4Ba + 4H^2O$, is insoluble in absolute alcohol, and crystallises in monoclinic prisms, which effloresce on the surface at a gentle heat, but do not give off the whole of their water till heated above 225° (Weinhold). A *tribasic salt*, $(C^6H^4S^2O^4)^2Ba^3 + 6H^2O$, is obtained by boiling the dibasic salt with barium carbonate; it is pulverulent, sparingly soluble in water even at the boiling heat; has a strong alkaline reaction; gives off 4 mol. water at 170° , and the rest at 225° (Städeler). The *neutral lead salt* crystallises by slow evaporation in needles, and is easily resolved in aqueous solution into basic and acid salt. A *basic lead salt*, $2C^6H^4S^2O^4Pb.PbO + 5H^2O$, separates on cooling from the aqueous solution of the neutral salt in crystalline scales feeling like tale. It forms easily soluble double salts with ammonium phenyl-disulphate, and with basic lead acetate (Weinhold).

PHLORETIC ACID. $C^6H^4O^3$.—This acid is isomeric with hydrocoumaric, or melilotic, and hydroparacoumaric acids, all three having the composition of oxyphenyl-propionic acid, $C^6H^4\left\{\begin{smallmatrix} OH \\ C^3H^3O^2 \end{smallmatrix}\right.$. Now hydrocoumaric acid is converted by fusion with potash into salicylic acid, and hydroparacoumaric acid into paraoxybenzoic acid. It might therefore be expected that phloretic acid when similarly treated would yield oxybenzoic acid. According to Barth, however (*Ann. Ch. Pharm.* clii. 96), it also yields paraoxybenzoic acid. It follows therefore that the relation of phloretic acid to its two isomerides cannot be that of an ortho-compound to a meta- and a para-compound. See ISOPHLORETIC ACID (*infra*).

PHLORETIN. On the preparation of this substance from a constituent of the root-bark of the apple-tree, see page 189.

PHLORIZIN. $C^{21}H^{24}O^{10}$ (iv. 493).—By treating this substance with acetyl chloride or acetic anhydride it is possible to replace five of its hydrogen-atoms by acetyl; it may therefore be supposed to contain five atoms of hydroxyl, and represented by the formula $C^{21}H^{19}O^5(OH)^5$ (Schiff, *Zeitschr. f. Chem.* [2] v. 519).

Isophlorizin. $C^{21}H^{24}O^{10}$ (Rochleder, *ibid.* iv. 741).—This substance occurs in the leaves of the apple-tree. It forms thin silvery needles half an inch long, which, like phlorizin, begin to melt at 105° . It dissolves easily in ammonia to a pale yellow liquid, which, after exposure to the air for a short time, becomes brownish-violet, and after the ammonia has evaporated, solidifies to a mass of colourless crystals sparingly soluble in cold water. Isophlorizin is precipitated from its aqueous solution by basic lead acetate, a property which may be made available for separating it from the decoction of apple-leaves.

The aqueous solution of isophlorizin heated with sulphuric acid, is resolved, much more quickly than phlorizin, into glucose and isophloretin, $C^{15}H^{14}O^3$, a compound distinguished from phloretin by its easy solubility in ether. Isophloretin heated for some minutes with very strong potash-ley is resolved into phloroglucin and isophloretic acid, $C^9H^6O^3$, the former of which may be dissolved out by ether, and the isophloretic acid separated from the potassium salt by sulphuric acid (for details of purification see the original paper). It separates from aqueous solution, by evaporation in a vacuum over sulphuric acid, in large crystals melting at 129° . It is distinguished from phloretic acid by not forming a green solution with ferric chloride; from hydrocoumaric acid (melting at 82°) by its much higher melting point; and from hydroparacoumaric acid, which melts at 125° , by the power which the latter possesses of reducing an alkaline cupric solution. Isophloretic acid is perhaps the ortho-modification of the acid $C^9H^6O^3$, but its reaction with fused potash has not been investigated.

PHLOROGLUCIN. $C^6H^4O^3 = C^6H^4(OH)^3$.—This triatomic phenol is produced by the decomposition of a great number of organic substances. Its formation from phloretin, quercetin, and morintannic acid is noticed in vol. iv. p. 593. It is also produced in the following reactions: 1. Together with protocathechuic acid, by the action

of melting potash on catechin, scoparin, luteolin, horse-chestnut tannin, and the red body formed by heating this tannin in an atmosphere of carbon dioxide:

(Malin, *Ann. Ch. Pharm.* cxxxiv. 118. Hlasiwetz, *ibid.* cxxxviii. 190. Rochleder, *Bull. Soc. Chim.* [2] viii. 115, 122). Ratanhia-red, tormentil-red, and the phloraphene of the oak have the same composition as horse chestnut-red, and are decomposed by fusion with potash in the same manner (Grabowski, *Jahresb.* 1867, p. 483; *Zeitschr. f. Chem.* [2] iv. 508. Rembold, *ibid.* 571).—2. Together with protocatechuic acid, paraoxybenzoic acid, and other products, by fusing dragon's blood or gamboge with caustic potash (Hlasiwetz a. Barth, *Jahresb.* 1865, p. 575; 1866, pp. 628, 631).

Phloroglucin heated to 140° with saturated aqueous *hydriodic acid* is not reduced (even in presence of phosphorus), but is converted, by abstraction of water, according to the equation $2\text{C}^8\text{H}^6\text{O}^3 - \text{H}^2\text{O} = \text{C}^{12}\text{H}^{10}\text{O}^3$, into a new body which crystallises in nearly tasteless scales, slightly soluble in warm water and alcohol, insoluble in ether, and consisting of $\text{C}^{12}\text{H}^{10}\text{O}^3 + 2\text{H}^2\text{O}$. The water is given off at 120° (Hlasiwetz, *Zeitschr. f. Chem.* [2] i. 613).

A moderately dilute solution of phloroglucin mixed with a similar solution of *quinine sulphate* slightly acidulated with sulphuric acid, yields large concentrically grouped needles consisting of a compound of quinine sulphate and phloroglucin, $\text{C}^{26}\text{H}^{22}\text{N}^2\text{O}^8 \cdot \text{SO}^4\text{H}^2 \cdot \text{C}^8\text{H}^6\text{O}^3 + 2\text{H}^2\text{O}$. Orcin and resorcin form similar compounds with quinine sulphate (Hlasiwetz, *loc. cit.*).

PHLOROL or **PHLORYL ALCOHOL**, $\text{C}^8\text{H}^{10}\text{O} = \text{C}^8\text{H}^9\left\{\begin{smallmatrix} \text{CH}^2(\text{CH}^3) \\ \text{OH} \end{smallmatrix}\right.$, is one of the constituents of beech-tar creosote, and is obtained by repeated fractional distillation of the portion boiling between 217° and 220°. When dehydrated by distillation over sodium, it forms a colourless oily liquid boiling at 219°–220°, and gradually turning reddish when exposed to light (Marasse, *Ann. Ch. Pharm.* clii. 76).

PHLORONE. $\text{C}^8\text{H}^6\text{O}^2$.—This body, homologous with quinone, was discovered by Rommieu a. Bouillon (iv. 496), who obtained it by oxidising coal-tar creosote with sulphuric acid and manganese dioxide. Gorup-Besanez a. von Rad (*Zeitschr. f. Chem.* [2] iv. 560) have obtained it in like manner from that kind of Rhenish beech-tar creosote which consists mainly of cresol. The liquid mixed with 1½ times its weight of strong sulphuric acid, is left to stand for 24 hours, then diluted with 6 vol. water, and distilled at a gentle heat with 1½ times its weight of manganese dioxide. A yellow liquid then passes over, which soon deposits phlorone in yellow crystals and solidifying oily drops, while the condensing tube becomes filled with long yellow needles. The crystals are collected, the yellow distillate is agitated with ether, the ethereal solution evaporated, and the crystals thus obtained, together with those first deposited, are recrystallised from alcohol. In preparing phlorone from coal-tar creosote, it is also necessary to leave the mixture of the creosote with sulphuric acid to stand till it no longer becomes turbid on addition of water; otherwise it yields by oxidation a brown liquid, but no phlorone. Cresol boiling at 198° yields abundance of phlorone when oxidised as above; but xylylic phenol boiling at 214° yields only a brown unctuous mass, with very little phlorone. Guaiacol prepared by dry distillation of guaiac resin yields a body very much like phlorone, but possibly consisting of its next lower homologue (v. Rad, *Ann. Ch. Pharm.* cli. 158; *Zeitschr. f. Chem.* [2] v. 712).

Phlorone crystallises in golden-yellow oblique rhombic prisms, which when heated give off a pungent odour, attacking the eyes and mucous membranes; it sublimes without decomposition at a stronger heat, and volatilises even at ordinary temperatures. It is heavier than water, melts at a temperature above 100° (v. Rad; at 61°–62° according to Rommieu a. Bouillon), dissolves sparingly in cold, easily in boiling water, also

in alcohol and ether. Its solutions colour the skin deep brown. Sulphuric acid dissolves it with yellow colour; alkalis impart to its solutions a brown colour, which disappears on addition of sulphuric acid. Dilute nitric acid dissolves it with yellow colour; with strong hydrochloric acid at the boiling heat it forms a brown solution which on cooling deposits white crystals of chlorhydrophlorone. With solid potash it forms a green mass. Phlorone solutions are decolorised by sulphurous acid and stannous chloride; ferric chloride colours them brown; hydrogen sulphide produces a precipitate.

Chlorophlorones (v. Rad, *loc. cit.*).—When dry chlorine is passed over moderately heated phlorone as long as hydrochloric acid continues to be evolved, the phlorone deliquesces to a yellow liquid, which on cooling deposits crystals, separable by means of alcohol into monochlorophlorone and dichlorophlorone, the former being the more soluble of the two. The same products are obtained by treating phlorone with hydrochloric acid and potassium chlorate.

Monochlorophlorone, $C^6H^5ClO^2$, crystallises in yellow needles melting below 100° to a brown liquid which resolidifies in the crystalline form on cooling. It has a peculiar aromatic odour, and dissolves easily in alcohol, ether, and acetic acid. Its solution in weak alcohol, boiled and left to cool, deposits a brown crystalline body, perhaps brown chlorhydrophlorone. When sulphurous acid gas is passed into warm water in which monochlorophlorone is suspended, the liquid on cooling deposits colourless crystals of monochlorohydrophlorone. Strong sulphuric acid dissolves monochlorophlorone, forming a deep yellow solution; potassium nitrite heated with it produces a fine red-brown colour. Its solution in acetic acid is coloured by soda-ley first green, then brown; the alcoholic solution is immediately coloured brown by soda or ammonia.

Dichlorophlorone, $C^6H^4Cl^2O^2$, forms light yellow unctuous laminae very slightly soluble in cold alcohol, easily in hot alcohol, boiling acetic acid, and ether; it dissolves with yellow colour in strong sulphuric acid, and is turned brown in alcoholic solution by soda, ammonia, and ferric chloride.

Hydrophlorone, $C^6H^5O^2$, is produced by passing sulphurous acid gas into a saturated aqueous solution of phlorone containing phlorone in suspension, till all the crystals have become colourless. It crystallises from hot water in colourless nacreous laminae, melts and sublimes when heated, dissolves easily in water, especially when heated, also in alcohol and ether. Ammonia colours the solutions brown, changed to dark red by heating or by contact with the air. With soda-ley a green colour is produced, becoming brown in contact with the air. By boiling with ferric chloride, dilute nitric acid, or silver nitrate, hydrophlorone is oxidised to phlorone, in the latter case with precipitation of metallic silver. Boiled with solution of cupric acetate it throws down cuprous oxide, and emits a strong odour of phlorone. With solid potash it forms a dark green mass. Fuming sulphuric acid dissolves it, with red colour, and the solution, diluted with water and neutralised with barium carbonate, contains a barium salt very soluble in water, insoluble in absolute alcohol. The aqueous solution of this acid colours ferric chloride dark brown, reduces silver salts, and forms a white precipitate with lead acetate.

Chlorhydrophlorone, $C^6H^5ClO^2$, is prepared by boiling phlorone crystals with strong hydrochloric acid. After repeated crystallisation from hot water it forms colourless silky needles, melting when heated to a brown liquid which solidifies to a colourless crystalline mass, and subliming with partial decomposition in colourless shining laminae mixed with violet needles; it dissolves easily in hot water, alcohol, and ether. Solid chlorhydrophlorone is coloured violet by ferric chloride and forms a green mass with potash. Its solutions are coloured brown by ammonia and fixed alkalis, reduce silver nitrate when heated, giving off the odour of chlorophlorone, and precipitate cuprous oxide when heated with cupric nitrate (v. Rad).

Dichlorhydrophlorone, $C^6H^4Cl^2O^2$, is produced by passing sulphurous acid gas into water in which dichlorophlorone is suspended, and warming the liquid on the water-bath till the yellow laminae become colourless; it is purified by washing with cold water, crystallisation from boiling water, and finally from moderately heated acetic acid. It sublimes with partial decomposition, yielding dark brown needles which burn with green-edged flame when heated on platinum foil. It dissolves sparingly in cold, easily in hot water, very easily in ether, alcohol, and strong acetic acid. In potash-ley it dissolves with green colour, changing to brown-red; in warm sulphuric acid with deep brown colour. The alcoholic solution is coloured brown by ammonia, and then yields with hydrochloric acid a violet flocculent precipitate. It reduces silver nitrate and cupric acetate, and is converted by hydrochloric acid and potassium chlorate into yellow crystalline laminae. With ferric chloride it immediately yields a violet flocculent precipitate, perhaps analogous to violet dichlorhydroquinone.

Phlorone may be formulated either as ethyl-quinone, $C^6H^4(C^2H^3)O^2$, or as dimethyl-quinone; but, since the highest chlorinated product obtainable from it by the action of chlorine or of hypochlorous acid, is dichlorophlorone, it appears to have only two atoms of hydrogen easily replaceable by chlorine, and is therefore most probably dimethyl-quinone; in like manner dichlorhydrophlorone may be regarded as dimethyl-hydroquinone:

PHLORYL ALCOHOL. Syn. with **PHLOROL** (p. 927).

PHOSENE. See **PHOTENE**.

PHOSGENE. Syn. with **CARBON OXYCHLORIDE** (p. 405).

PHOSPHAMIC ACIDS. Gladstone has described three phosphamic acids derived from pyrophosphoric acid by substitution of 1, 2, and 3 at. amidogen for hydroxyl (iv. 766); these may be formulated as follows:

The following are additional details respecting these acids (*Chem. Soc. J.* [2] vi. 64):

Pyrophosphamic acid, $P^2(NH^2)H^2O^4$, is produced by the decomposition of the tetraphosphamic acids (p. 931); also by the following methods: *a.* When pyrophosphoric acid is saturated with ammonia, and barium hydrate is added not in excess, a white precipitate of barium pyrophosphamate is obtained; with excess of baryta, pyrophosphate is the only product. A similar result is produced when lead acetate or ferric chloride is added instead of barium hydrate.—*β.* A salt having the composition of ferric pyrophosphamate is likewise formed when insoluble ferric pyrophosphate is precipitated in presence of a large quantity of sal-ammoniac; or by dissolving ferric pyrophosphate in ammonia and precipitating with sulphuric acid; or again by precipitating soluble ferric pyrophosphate from its solution in sulphuric acid by ammonia. The compound thus obtained differs however from the ferric pyrophosphamate previously described, in being soluble in sodium pyrophosphate and in ferric chloride, slightly also in water, and in being decomposed by cold dilute sulphuric acid. It may therefore be regarded either as a soluble modification of ferric pyrophosphamate, $[P^2(NH^2)O^4]^2Fe^2 + 2H^2O$, or perhaps only as ammonio-ferric pyrophosphate, $(P^2O^7)^2(NH^2)^2Fe^2$. It is not converted into the ordinary salt by boiling with very dilute sulphuric acid. Copper salts give similar results.

Pyrophosphodiamic acid, $P^2(NH^2)^2H^2O^4$, is most distinctly characterised by the white flocculent precipitate thrown down from its hot strongly acid solution by ferric chloride; this precipitate does not melt when heated, but blackens, gives off ammonia, and forms a sublimate, whereas ferric pyrophosphate merely melts without blackening.

Pyrophosphotriamic acid, $P^2(NH^2)^3HO^4$, is most abundantly produced by saturating phosphorus oxychloride (not cooled) with ammonia gas, heating the product to 220°, and boiling it for a short time with water.

With regard to the formation of these amidated acids from phosphorus oxychloride. Gladstone supposes that the oxychloride reacts in the cold with 2 mol. ammonia, so as to form the amide $P(NH^2)Cl^2O$, and at higher temperatures with 4 mol. ammonia to form the amide $P(NH^2)^2ClO$. The formation of pyrophosphodiamic acid from these amides takes place in the manner shown by the following equations:

Pyrophosphamates are formed by the action of metallic chlorides on the diamia acid, thus :

Pyrophosphotriamic acid appears to be formed from an amidated oxychloride of unknown composition.

TETRAPHOSPHAMIC ACIDS (Gladstone, *Chem. Soc. J.* [2] vi. 261).—These acids, also produced by the action of water on the amides of phosphorus oxychloride, may be derived from tetraphosphoric acid, $P^4(HO)^4O^4$, the acid corresponding to the phosphates, $P^4(MO)^4O^4$ (iv. 537); thus :

When phosphorus oxychloride is saturated at a low or moderately high temperatures with ammonia, a white mass is formed which dissolves completely in water, with exception of a small quantity of pyrophosphotriamic acid; and alcohol added to this solution throws down either a viscid liquid or light solid precipitate, sometimes also a glutinous substance which appears to be a mixture of the other two. The liquid compound, when purified by washing with alcohol, repeated precipitation by alcohol from its aqueous solution, and drying in a vacuum, has the composition $P^2N^2H^{10}O^{11}$. It is very hygroscopic, sustains a temperature of 100° without decomposition, gives off ammonia when treated with cold potash-ley, and is decomposed by hydrochloric acid into orthophosphoric acid and sal-ammoniac. With ammonia it forms a liquid compound slightly soluble in water, insoluble in alcohol, from which the original substance is separated by dilute sulphuric acid. In aqueous solution it forms solid precipitates with many metallic salts, but appears at the same time to undergo alteration, inasmuch as neither of these compounds contains more than 3 at. nitrogen to 4 at. phosphorus, and they all, when decomposed by acids, yield solid tetramides and pyrophosphamic acids. From its reaction with potash, the compound $P^2N^2H^{10}O^{11}$ may be regarded as the triammonium salt of *tetraphosphodiamic acid*, $P^2(NH^2)^2H(NH^4)^3O^{11}$.

Tetraphosphotetramic acid, $P^4(NH^2)^4H^2O^4$, is obtained either by decomposing the liquid compound with a metallic salt, and the precipitate with an acid, or more readily by dissolving the above-mentioned glutinous body in water, decomposing it with a large excess of a mineral acid, precipitating with alcohol, and repeating this treatment till the precipitate becomes sparingly soluble in water, and friable after drying. It is likewise produced by boiling the liquid acid with water for several hours, or by treating it with alkalis or strong acids. Its formation is usually accompanied by that of pyrophosphodiamic or pyrophosphotriamic acid. It combines with bases, and is separated by acids from the resulting compounds, apparently unaltered. It appears to form two ammonium salts, one of which, precipitated by alcohol from the aqueous solution, has the composition $P^4(NH^2)^2H(NH^4)^2O^4$, and gives off all its ammonia in a vacuum. Two silver salts, $P^4N^4H^4Ag^4O^4$ and $P^4N^4H^4Ag^4O^4$, have also been examined.

Tetraphosphopentazotic acid, $P^4N^2H^2O^4$.—When phosphorus oxychloride is rapidly saturated with ammonia, the mass becomes strongly heated, and when treated with water leaves a body different from pyrophosphotriamic acid. This compound is obtained in greater purity when the product, saturated with ammonia, is heated above 200° , but not to the volatilising point of sal-ammoniac, and then exhausted with water. The insoluble residue consists of tetraphosphopentazotic acid. It is decomposed with moderate facility by water, and quickly at the boiling heat, with formation of pyrophosphamic acids; a similar transformation takes place gradually in the dry state and at ordinary temperatures. The salts of this acid are nearly or quite insoluble. The ammonium salt, $P^4N^2H^2(NH^4)^2O^4$, and the potassium salt, $P^4N^2H^2KO^4$, have been examined; also the silver, copper, and lead salts, which, however, have not been obtained of constant composition.

When tetraphosphopentazotic acid is treated with neutral or slightly acidulated silver nitrate, a pale yellowish-brown precipitate is formed, having nearly the composition $P^4N^2H^2Ag^2O^4$. Gladstone regards this salt as the silver salt of *tetraphosphotetramic acid*, $P^4(NH^2)^4H^2O^4$ (*Chem. Soc. J.* [2] vii. 22).

PHOSPHAMIDES. By passing dry ammonia gas into phosphorus oxychloride, and digesting the product with water to dissolve sal-ammoniac, Schiff (iv. 498) obtained phosphotriamide, $PO(NH^2)^3$. Gladstone, on the other hand, did not obtain this compound, but only the intermediate bodies $POCl^2(NH^2)$ and $POCl(NH^2)^2$ (*Chem. Soc. J.* [2] vii. 16). Schiff, however, in a recent paper (*Zeitschr. f. Chem.* [2] v. 609) again asserts the formation of the phosphotriamide, and points out that in

order to ensure the complete replacement of the chlorine in POCl^3 by amidogen, it is necessary to use *perfectly dry ammonia gas*, to pulverise the mass frequently during the operation, again treat it with ammonia, while warmed, and finally leave it for some time in the pulverised state in a vessel filled with ammonia gas, agitating it frequently to promote the absorption. If phosphoric acid be represented as $\text{P} \begin{Bmatrix} \text{O.H} \\ \text{OH} \end{Bmatrix}$

and phosphorus oxychloride accordingly as $\text{P} \begin{Bmatrix} \text{O.Cl} \\ \text{Cl} \end{Bmatrix}$, it will be seen that one atom of

chlorine in the latter may have a different function from the rest, and may be more difficult to replace by amidogen. If the oxychloride used retains a small quantity of pentachloride, the phosphotriamide formed as above will contain a certain quantity of chlorine, inasmuch as the pentachloride is decomposed by ammonia according to one of the following equations:

or

In the latter case, on dissolving out the sal-ammoniac by water, phosphodiamide would be formed:

Phospho-phenyldiamide or *Phospho-dianilide*, $\text{N}^2(\text{PO})^{\text{H}}(\text{C}^6\text{H}^3)^2$, is formed in like manner by the action of phosphorus pentachloride on aniline, and remains, on treating the product with water, as a white flocculent substance. Heated with water it melts somewhat below 100° and is gradually converted into aniline phosphate. With phosphorus trichloride, aniline forms the *trianilide of phosphorous acid*, together with aniline hydrochloride:

The trianilide which is the less soluble part of the crude product is gradually converted by the action of water into anilino phosphite (Schiff).

Phenyl-sulphuryl-dichlorophosphamide, $\text{C}^6\text{H}^3.\text{SO}^2.\text{NH}.\text{PCl}^2$, is formed by the action of phosphorus pentachloride on the so-called benzene-sulphamide:

The crude product poured while still warm on a porous plate, and then left for some time over sulphuric acid, solidifies at first, but afterwards becomes semifluid, an oily liquid sinking into the plate. The remaining solid compound crystallises from ether in large shining crystals, which must be enclosed immediately in a sealed tube to preserve them from alteration. They melt at 130° – 131° , and are reconverted into benzene-sulphamide by contact with moist air, or more quickly by water or alcohol (Wichelhaus, *Zeitschr. f. Chem.* [2] vi. 54).

PHOSPHANILINE. $(\text{C}^6\text{H}^3\text{P}^{\text{H}})^{\text{N}^2}$ (Tait, *Zeitschr. f. Chem.* [2] i. 648).—When well-cooled aniline is mixed by drops with phosphorus trichloride, violent reaction takes place, and an unctuous mass is formed, the aqueous solution of which, freed from excess of aniline by passing through a wet filter, solidifies by evaporation in a vacuum over sulphuric acid to a mass of needle-shaped crystals, consisting of the hydrochloride of phosphaniline formed by direct combination of aniline and phosphorus trichloride:

The *platinochloride*, $2(\text{C}^6\text{H}^3\text{PN}^3.3\text{HCl}).3\text{PtCl}^4$, forms pale yellow granular crystals soluble in water and alcohol, but not in ether. A *zincchloride*, $2(\text{C}^6\text{H}^3\text{PN}^3.3\text{HCl}).3\text{ZnCl}^2$, is obtained in somewhat deliquescent needles soluble in alcohol, by dissolving zinc in the acidulated solution of the hydrochloride, and evaporating at about 93° . The hydrochloride also forms double salts with cadmic, cupric, and mercuric chlorides. Bromine-water produces in the solution of the hydrochloride a brown precipitate containing tribromaniline. Phosphaniline itself has not been isolated.

PHOSPHIDE, CYANETHYLIC. $P \begin{Bmatrix} \text{CN} \\ \text{C}^2\text{H}^3 \\ \text{H} \end{Bmatrix}$.—Produced by the action of gaseous

hydrogen phosphide on cyanogen chloride dissolved in ether. The reaction takes place easily at 100° , and on distilling off the ether, the cyanethylic phosphide remains as a liquid, which solidifies in a dry atmosphere. It crystallises in rhombic plates, melts at 49° – 50° , volatilises without decomposition, and dissolves easily in water, alcohol, and ether. Its formation is represented by the equation:

When oxidised it gives off an odour of aldehyde or acetic acid (Darmstädter a. Henniger, *Compt. rend.* lxx. 404).

PHOSPHONITRILE. This name is now applied by Gladstone to the compound PNO (Gerhardt's biphosphamide), which may also be regarded as phosphomonamide, $\text{N}(\text{PO})^m$. It is produced by strongly heating the product obtained by the action of ammonia on phosphorus oxychloride, being formed by abstraction of 2HCl from the compound $\text{PCl}_2(\text{NH}^2)\text{O}$, or of NH^4Cl from $\text{PCl}(\text{NH}^2)_2\text{O}$ (Gladstone, *Chem. Soc. J.* [2] vii. 18).

PHOSPHONITRILIC ACID. P^2NHO^4 .—From observations by Holmes, reported by Gladstone (*ibid.* 79), it appears that the potassium salt of this acid is obtained by igniting potassium pyrophosphotriammate:

The ammonium salt appears to be formed by ignition of pyrophosphotetramic acid:

PHOSPHORUS. On the atomicity of phosphorus, see Wichelhaus (*Ann. Ch. Pharm. Suppl.* vi. 257; *Jahresb.* 1868, p. 148).

Modifications.—Hittorff (*Pogg. Ann.* cxxvi. 193; *Jahresb.* 1865, p. 127) has obtained a crystallised modification of red phosphorus, by heating amorphous phosphorus to 530° in a sealed vacuum glass tube, and allowing the vapour to condense in the upper part of the tube, heated only to 447° ; the phosphorus then collects in nodular groups of microscopic needles. It may however be obtained in larger quantity and more distinct crystals, by separation from a solution of phosphorus in lead. A wide tube of difficultly fusible glass is filled to one-fourth with phosphorus, and the remaining three-fourths with lead, while a stream of carbon dioxide is passed through it. It is then exhausted, sealed, enclosed in an iron tube packed with magnesia, and heated for several hours over a number of Bunsen burners. On cooling, the surface of the lead is found to be covered with black, metallically lustrous, laminar crystals, unalterable in the air, while the interior of the lead is traversed by small but dense and well-defined crystals. The superficial crystals are very thin, mostly bent and transversely striated, whereby they acquire the aspect of rows of prismatic crystals; they are yellowish-red by transmitted light. The crystals enclosed in the mass of lead are isolated by treating this mass for several days with nitric acid of sp. gr. 1.1 (the phosphorus, as the more electro-negative body, not being attacked), and purified from all but a trace of lead by boiling with strong hydrochloric acid. They have then a black-violet colour, and appear under the microscope as rhombohedrons nearly approaching to the cube, and probably isomorphous with arsenic, antimony, and bismuth. The sp. gr. of the laminar and also of the dense crystals (allowance being made for the small quantity of lead which they retain) is 2.34 at 15° : hence the specific volume of crystallised red phosphorus is 13.25, agreeing with that of crystallised arsenic, according to the specific gravity 5.67 determined by Hittorff. The crystallised red phosphorus is even less volatile than amorphous phosphorus, and like the latter conducts electricity feebly in comparison with metals, but easily as compared with ordinary phosphorus. Hittorff designates this variety of phosphorus as *crystallised metallic*, red amorphous phosphorus as *amorphous metallic*, and ordinary colourless phosphorus as *ordinary non-metallic*.

Ordinary phosphorus is most easily converted into amorphous phosphorus by heating it to the temperature of boiling sulphur in a thick glass tube (or an iron vessel for larger quantities) exhausted and sealed. The transformation is attended with evolution of heat, the temperature of the phosphorus vapour exceeding that of the heated air-bath by about 75° . The conversion of ordinary into amorphous phosphorus in presence of iodine takes place at 160° . Respecting the vapour-densities and vapour-tensions of the three varieties, see the memoir above cited; also *Phil. Mag.* [4] xxxi. 311; *Chem. News*, xiii. 133; *Jahresb.* 1865, p. 130. On the conversion of ordinary

into amorphous phosphorus, and the contrary, see Lemoine (*Bull. Soc. Chim.* [2] viii. 71; *Jahresb.* 1867, p. 138).

From experiments on the formation of white phosphorus (iv. 503), Baudrimont (*Bull. Soc. Chim.* [2] v. 206) concludes that this modification is neither crystallised nor allotropically modified phosphorus, but ordinary phosphorus having its surface corroded by oxygen dissolved in the water in which it is kept; in de-aerated water the white film is not produced. The presence of water appears however to be necessary, inasmuch as phosphorus does not lose its transparency when it oxidises in the air.

Fusion of Phosphorus.—Phosphorus fused under water does not solidify at temperatures above 32°C , either by the most violent agitation in a closed tube, or in an open tube by contact with any solid body, even with amorphous phosphorus heated to the same temperature; immediately however if brought in contact with ordinary phosphorus (a glass tube on which phosphorus has been rubbed), or if a solid body immersed in the fused mass is rubbed against the sides of the tube or against another immersed body. Particles of glass, for example, heated with the phosphorus do not prevent it from remaining fluid as it cools, but on shaking the tube they instantly induce solidification, even at 43° , the temperature then rising to 44° (Gernez, *Compt. rend.* lxxiii. 217).

Sublimation.—According to Blondlot (*ibid.* 397), colourless phosphorus may be sublimed in a rarefied atmosphere of nitrogen at comparatively low temperatures, *e.g.* by melting phosphorus in a small flask previously sealed, and, after the oxygen of the confined air has been absorbed, immersing the lower part of the flask in an air-bath heated to 40° ; the phosphorus then sublimes in the neck in colourless microscopic cubic crystals having an adamantine lustre.

Oxidation.—Groves (*Pharm. J. Trans.* [2] vi. 643) found that amorphous phosphorus which had been kept for two years in a cracked vessel, was converted, to the extent of about 16 p. c. into phosphorous and phosphoric acids. The damp mass emitted the odour of oxidising phosphorus, but was not luminous in the dark.

According to Blondlot (*Zeitschr. f. Chem.* [2] iv. 375), the direct product of the slow oxidation of phosphorus is not phosphoric acid; and the phosphorous acid contained in the so-called *phosphatic acid* (iv. 499) is produced by the action of the free phosphorus on phosphoric acid previously formed. White phosphorus fumes consist wholly of phosphoric acid. The formation of ozone in the oxidation of phosphorus does not take place at temperatures below 12° . Respecting the composition of phosphorus fumes, see also W. Schmid (*J. pr. Chem.* xlviii. 414; *Jahresb.* 1866, p. 113).

Phosphorus as a Test for Metals.—A solution of phosphorus in carbon bisulphide filtered through asbestos, and then shaken up with water, whereby a snow-white turbidity is produced, affords a very delicate test for certain metals. All copper-solutions, even ammoniacal, give with this reagent a brown-red precipitate, silver-solutions a black, mercuric solutions a brownish-yellow, gold-solutions a violet precipitate. Still greater delicacy may be obtained by the use of filtering-paper moistened with the liquid above mentioned, and not quite dried (W. Schmid, *Zeitschr. f. Chem.* [2] iv. 161). On the reactions of phosphorus with metals, see also Nickles (*ibid.* v. 351).

Detection and Estimation of Phosphorus.—The presence of phosphorus either in inorganic or in organic bodies may be detected by heating the solid substance (or the charcoal in the case of organic bodies) with about half its bulk of magnesium filings in a test-tube. The mixture becomes phosphorescent in the dark, and red phosphorus is deposited on the sides of the tube, the greater part of the phosphorus, however, uniting with the magnesium. On moistening the contents of the tube after cooling, with water, gaseous hydrogen phosphide is given off (Schönn, *Zeitschr. anal. Chem.* 1869, pp. 53, 55; *Zeitschr. f. Chem.* [2] v. 664).

In applying the process given by Dumas and by Blondlot (iv. 520) for the detection of phosphorus, Otto (*Zeitschr. f. Chem.* [2] ii. 733) recommends that the gas be passed through a U-tube containing pumice soaked in potash-ley, in order to remove hydrogen sulphide or sulphurous oxide; without this precaution, the emerald-green colouring of the flame, even when a rather large quantity of phosphorus is present, partly disappears, and is disguised by a blue flame, arising, as shown by Barrett (*Phil. Mag.* [4] xxx. 321), from the presence of sulphur-compounds.

For the estimation of phosphorus in iron and steel, Spiller (*Chem. Soc. J.* [2] iv. 148) mixes the nearly neutralised solution of the metal in nitro-muriatic acid—after partial reduction with sulphurous acid and cooling to 20° – 24° —with sesquicarbonate of ammonia, till the precipitate, which is red at first, assumes a greenish colour. The

precipitate containing all the phosphoric acid is then dissolved in hydrochloric acid; the iron is precipitated by ammonium sulphide after addition of citric acid and ammonia; and in the filtrate freed from sulphur the phosphoric acid is precipitated as ammonio-magnesian phosphate.

Schlesing (*Zeitschr. f. Chem.* [2] iv. 567; *Jahresh.* 1868, p. 856) estimates phosphorus in iron phosphide by igniting the pulverised compound in chlorine gas, passing the evolved phosphorus trichloride into water, and oxidising the resulting phosphorous acid to phosphoric acid by nitric acid. Tantin (*Chem. News*, xviii. 252) estimates phosphorus in iron by dissolving the iron in dilute hydrochloric acid, passing the evolved gas through potash-ley to remove hydrogen sulphide, and then into a solution of silver nitrate, which absorbs the hydrogen phosphide (and arsenide, if arsenic is present). The precipitated silver phosphide is treated with nitromuriatic acid, and the phosphoric acid thereby formed is precipitated as ammonio-magnesian phosphate.

Chlorine- and Bromine-compounds of Phosphorus.

According to Rathke (*Zeitschr. f. Chem.* [2] vi. 57), the statement of Carius that phosphorus pentachloride and carbon bisulphide yield, by their mutual action, sulphocarbonyl chloride, CSCl_2 , is incorrect. The products actually obtained are carbon tetrachloride and phosphorus sulphochloride, according to the equation: $\text{CS}_2 + 2\text{PCl}_5 = \text{CCl}_4 + 2\text{PSCl}_2$.

Phosphorus trichloride treated with 1 mol. absolute alcohol gives off a large quantity of hydrochloric acid, and the liquid product yields, by distillation between 90° and 125° , ethyl-phosphorous chloride, $\text{POC}^2\text{H}^5\text{Cl}$, which by fractional distillation is obtained as a transparent, colourless, strongly refracting liquid, fuming in the air, boiling constantly at 170° , and having a sp. gr. of 1.316 at 0° . Its formation is represented by the equation:

It is decomposed by water into alcohol and phosphorous acid. By bromine it is resolved, according to the equation,

into ethyl bromide and phosphorus oxychlorobromide, which may be separated by fractional distillation (Menschutkin, *Ann. Ch. Pharm.* cxxxix. 343).

Butyl-phosphorous chloride, $\text{POC}^4\text{H}^9\text{Cl}$, produced by the action of 2 mol. PCl_3 on 3 mol. butyl alcohol, boils between 154° and 156° , has a sp. gr. of 1.191 at 0° , and is decomposed by water in the same manner as the ethyl-compound. Amyl-phosphorous chloride, $\text{POC}^5\text{H}^{11}\text{Cl}$, obtained like the preceding, boils at 173° , has a sp. gr. of 1.109 at 0° , and reacts like the ethyl-compound with water and bromine (Menschutkin).

Phosphorus Oxychlorobromide, POCl_2Br , obtained as above, is a transparent, colourless, strongly refracting liquid, quickly turning yellow. It boils at 135° to 137° , has a sp. gr. of 2.059 at 0° , and is decomposed by water with formation of phosphoric acid (Menschutkin).

The oxychlorobromide, POCl_2Cl , produced in like manner by the action of chlorine on ethylphosphorous chloride, agrees in sp. gr. (1.66), boiling point (110°), and other properties, with phosphorus oxychloride obtained by the ordinary methods. The oxychloride, and phosphoric acid which is formed from it by the action of water, may therefore be represented by the following formulae:

Phosphoric acid thus appears to have the constitution of monoxyposphorous acid (Wichelhaus, *Zeitschr. f. Chem.* [2] iii. 321).

Sulphochloride. PSCl_2 .—Chevriér (*Compt. rend.* lxiii. 1003) prepares this compound by gradually adding 2 at. phosphorus to 3 mol. sulphur chloride heated nearly to boiling in a capacious flask, and distilling after the whole is dissolved, rejecting the portion which passes over below 125° :

By this method, 800 grms. of the sulphochloride may be prepared in the course of a day. According to A. v. Flemming (*Zeitschr. f. Chem.* [2] iv. 288), the product

obtained by Chevrier's method is not pure, but may be purified, with loss of a considerable portion, by agitating it with water, separating it as well as possible from the watery liquid, distilling, and rejecting the portion which first passes over at 110° . Chevrier (*ibid.* v. 442) has given several details respecting the properties and reactions of this body, but they are not of much importance.

According to L. Henry (*Deut. chem. Ges. Ber.* ii. 638), the sulphochloride is formed by direct combination of sulphur and the trichloride at 130° . It boils at 125° – 128° (compare iv. 606).

Hydrides. According to Rüdorff (*Zeitschr. f. Chem.* [2] ii. 637), the yellow body formed by the action of water on phosphorus di-iodide, commonly regarded as amorphous phosphorus, agrees in its properties with solid phosphorus hydride, P^2H or P^3H^2 . On adding phosphorus iodide to hot water, this compound is immediately separated, and non-spontaneously inflammable phosphorus tri-hydride is given off; in cold water the reaction takes place gradually. Rüdorff represents it by the following equation:

According to Commaille (*J. Pharm.* [4] viii. 321), the tri-hydride is rapidly evolved by the action of phosphorus on potash-ley even at ordinary temperatures; hence an error may arise in the analysis of gases, when, after treatment of the gas with potash, phosphorus is introduced to absorb oxygen, and comes in contact with the potash.

Oxides and Oxygen-acids of Phosphorus.

Phosphorous Acid. PH^3O^3 .—This acid is produced by atmospheric oxidation of hypophosphorous acid. A solution of barium hypophosphite decomposed by sulphuric acid, and exposed for a long time to the air, yielded, when neutralised with calcium carbonate, a precipitate of calcium phosphite (Rammelsberg, *Zeitschr. f. Chem.* [2] iv. 724).

When 1 mol. crystallised phosphorous acid and 1 mol. bromine are heated in a sealed tube to 100° , with frequent agitation, hydrobromic and metaphosphoric acids are produced:

With 3 mol. bromine to 4 mol. phosphorous acid, the products are orthophosphoric acid, hydrobromic acid, and phosphorus tribromide:

The action of iodine is not exactly analogous to that of bromine. With a small proportion of iodine, phosphorus iodide and metaphosphoric acid are found among the products. With a larger proportion of iodine, the products are orthophosphoric acid, hydriodic acid, phosphonium iodide, and phosphorus di-iodide:

(Gustavson, *Bull. Soc. Chim.* [2] viii. 29). According to Ordinaire (*Compt. rend.* lxiv. 363), 1 mol. phosphorous acid and 2 mol. bromine heated in a sealed tube, form, together with hydrobromic acid, a very deliquescent crystallised body, which he regards as monobromophosphorous acid; it is decomposed by boiling water, with formation of a new gelatinous acid. Dry chlorine at 100° acts in a similar manner. The formation of phosphoric acid was not observed in either case.

METALLIC PHOSPHITES.—The constitution of these salts has been carefully examined by Rammelsberg (*Berl. Akad. Ber.* 1866. p. 537; *Chem. Soc. J.* [2] v. 388; further *Pogg. Ann.* cxxxi. 263, 359; cxxxii. 481; *Jahresb.* 1867. p. 141). His experiments confirm the view advocated by H. Rose (*Pogg. Ann.* viii. 205; ix. 23, 215), that different phosphites contain different quantities of chemically combined or constitutional water, or its elements (exclusive of water of crystallisation), in opposition to that of Wurtz, according to which, all dry phosphites contain the same amount of constitutional water, namely 1 molecule. Rammelsberg does not however

regard the existence of the salts M^+HPO^3 (or $M^+H^2P^2O^6$) and $M^+H^+P^2O^7$ as demonstrating the existence of two different phosphorous acids, $H^+P^2O^6$ and $H^+P^2O^7$, or the evolution of hydrogen from heated phosphorous acid as a proof that the hydrogen does not exist therein in the form of water. He infers rather, from the whole of the facts observed, that both crystallised phosphorous acid and the metallic phosphites contain water ready formed, but more intimately combined than in other hydrates, so that it is not given off below 200° , and its elements take part in the decomposition of

the acid. The name phosphorous acid is applied by Rammelsberg to the group $\text{H}^4\text{P}^2\text{O}^5$, in which the four hydrogen-atoms are replaceable by metals. This quadribasic acid has not yet been obtained in the separate state, because the crystallised hydrate, $\text{H}^4\text{P}^2\text{O}^5 \cdot \text{H}^2\text{O}$, is resolved by heat into phosphoric acid and hydrogen phosphide.

The normal phosphites correspond to the hydrates:

and are represented, according to the equivalence of the metals which they contain, by the formulæ:

The normal phosphites of *barium*, *strontium*, and *calcium*, precipitated by ammonia or by sodium carbonate from the acid solution obtained by decomposing phosphorus trichloride with water, are constant in composition, but of loose finely crystalline structure, in consequence of which they obstinately retain a certain amount of hygroscopic water even at 100° . Nevertheless the *barium salt*, $\text{Ba}^2\text{H}^4\text{P}^2\text{O}^7$ (also the lead salt), may be regarded as anhydrous in the air-dried state (hygroscopic water = 1.5 to 1.9 p. c.). The *strontium salt*, $\text{Sr}^2\text{H}^4\text{P}^2\text{O}^7 + 2\text{H}^2\text{O}$, and the *calcium salt*, $\text{Ca}^2\text{H}^4\text{P}^2\text{O}^7 + 2\text{H}^2\text{O}$, give off part of their water of crystallisation at 100° , and are anhydrous when dried at 250° . The *magnesium salt* is obtained—by adding magnesium sulphate to the boiling aqueous solution of the trichloride nearly neutralised with sodium carbonate, or by neutralising the boiling solution with magnesium carbonate—as a white, sometimes crystalline precipitate. When produced in dilute solutions and left in the liquid for some time, it forms small distinct crystals containing $\text{Mg}^2\text{H}^4\text{P}^2\text{O}^7 + 12\text{H}^2\text{O}$; in the amorphous state its amount of water is somewhat less. The crystals exposed to the air or over sulphuric acid give off 7 mol. water and leave the salt $\text{Mg}^2\text{H}^4\text{P}^2\text{O}^7 + 5\text{H}^2\text{O}$, which is sometimes also formed by precipitation, and in that case gives off half its water over sulphuric acid. Rammelsberg likewise obtained, under circumstances not particularly specified, the salts $\text{MgHPO}^3 + 4\text{H}^2\text{O}$ and $\text{Mg}_2\text{H}_2\text{P}^2\text{O}^4$, with various quantities of crystallisation-water. With regard to the composition of *ammonio-magnesium phosphite*, Rammelsberg does not decide whether it should be represented by the formula $\text{Mg}^3(\text{NH})^2\text{H}^4\text{P}^2\text{O}^{12} + 16\text{H}^2\text{O}$, or by $\text{Mg}_2(\text{NH})^2\text{H}^4\text{P}^2\text{O}^{11} + 16\text{H}^2\text{O}$.

The *nickel salt*, $\text{Ni}^2\text{H}^4\text{P}^2\text{O}^7 + 6\text{H}^2\text{O}$, is obtained by adding nickel-carbonate to the nearly neutralised solution of the trichloride, and heating the liquid to the boiling point, as a green precipitate, which gives off half its water over sulphuric acid, the rest at 250° . The *cobalt salt*, $\text{CoHPO}^3 + 2\text{H}^2\text{O}$, prepared in like manner, likewise gives off half its water over sulphuric acid. The *manganese salt*, $\text{MnHPO}^3 + \text{H}^2\text{O}$, is thrown down as a reddish-white precipitate when the solution of phosphorus trichloride is mixed with manganous acetate and neutralised with ammonia; or when it is nearly saturated with manganous carbonate, and sodium carbonate is then added in quantity sufficient to produce a precipitate, but not to neutralise the acid reaction completely. When dried over sulphuric acid it contains $3\text{MnHPO}^3 + 2\text{H}^2\text{O}$. The *zinc salt*, $2\text{ZnHPO}^3 + 5\text{H}^2\text{O}$, is prepared like the magnesium salt, which it resembles in being more soluble in cold than in hot water. It remains unaltered over sulphuric acid, is converted between 100° and 120° into $\text{ZnHPO}^3 + 2\text{H}^2\text{O}$, and gives off the rest of its crystallisation-water at 250° . The anhydrous salt, ZnHPO^3 , is likewise obtained by spontaneous evaporation of a solution of the hydrated salt in phosphorous acid. Particular preparations, obtained apparently as above described, exhibited different amounts of water, sometimes for example corresponding to the formula $\text{Zn}^2\text{H}^4\text{P}^2\text{O}^7 + 3\text{H}^2\text{O}$. The *cadmium salt*, $\text{Cd}^2\text{H}^4\text{P}^2\text{O}^7 + 3\text{H}^2\text{O}$, gives off its water over sulphuric acid. The *lead salt* dried over sulphuric acid contains PbHPO^3 ; the *cupric salt*, $\text{CuHPO}^3 + 2\text{H}^2\text{O}$, is partially reduced even at 120° .

The normal phosphites of the alkaline-earth metals are resolved by heat into pyrophosphate and free hydrogen: e.g. $\text{Ca}^2\text{H}^4\text{P}^2\text{O}^7 = \text{Ca}^2\text{P}^2\text{O}^6 + 2\text{H}^2$; those of the heavy metals leave a mixture of pyrophosphate and phosphide: $7\text{M}^2\text{H}^4\text{P}^2\text{O}^7 = 6\text{M}^2\text{P}^2\text{O}^6 + \text{M}^2\text{P}^2 + 7\text{H}^2$. Small quantities of free phosphorus and of hydrogen phosphide are also produced by the reducing action of the hydrogen on the pyrophosphate.

Acid Phosphites.—A solution of the normal barium salt in the requisite quantity of phosphorous acid yields, by spontaneous evaporation, radiate groups of white silky needles of the salt $\text{Ba}^2\text{H}^2\text{P}^2\text{O}^3 \cdot 3\text{H}^2\text{PO}^3 + 2\text{H}^2\text{O}$. A solution of 1 mol. of the normal salt in rather more than 2 mol. phosphorous acid, yields crystals, not of the biacid, but of the sesqui-acid salt, $\text{Ba}^2\text{H}^2\text{P}^2\text{O}^3 \cdot \text{H}^2\text{PO}^3 + 8\text{H}^2\text{O}$, which melts when heated and gives off hydrogen phosphide at 250° . The biacid salt crystallises from the solution of the two preceding salts by evaporation over sulphuric acid, with an amount of water corresponding to the formula $\text{BaH}^2\text{P}^2\text{O}^3 + 2\text{H}^2\text{O}$; ammonia added to the aqueous solution of this salt throws down, not an acid salt as supposed by Rose, but the normal salt. **Zinc Salts.**—By dissolving the neutral zinc salt in phosphorous acid, Rammelsberg obtained various crystallised compounds corresponding to the formulae $\text{Zn}^2\text{H}^2\text{P}^2\text{O}^3 + \text{H}^2\text{O}$, $\text{Zn}^2\text{H}^2\text{P}^2\text{O}^3 + \text{H}^2\text{O}$, and $\text{Zn}^2\text{H}^2\text{P}^2\text{O}^3$. An acid uranic phosphite, $(\text{UO})^2\text{H}^2\text{P}^2\text{O}^3 + 6\text{H}^2\text{O}$, is obtained, by adding recently precipitated ammonium uranate to the aqueous solution of phosphorus trichloride, as a gradually formed yellow precipitate, which on exposure to the air dries up to hard translucent lumps.

Phosphorous Ethers.—Rammelsberg represents these ethers by formulae analogous to those of the acid metallic phosphites as follows:

Phosphoric Anhydride, Acid, and Salts. On the preparation of phosphoric anhydride on the large scale, see Grabowski (*Ann. Ch. Pharm.* cxxvi. 119; *Jahresb.* 1865, p. 135).

Mich. Pettenkofer (*Ann. Ch. Pharm.* cxxxviii. 57; *Jahresb.* 1866, p. 138) describes a method of preparing phosphoric acid, simultaneously with hydriodic acid, by treating ordinary phosphorus with iodine and water, distilling off the hydriodic acid, and oxidising the residue, which contains phosphorous and phosphoric acids, with nitric acid.

According to Krämer (*Zeitschr. f. Chem.* [2] v. 543), phosphoric acid may be obtained in transparent prismatic crystals, by evaporating from an aqueous solution, the strength of which is known from its specific gravity, such a quantity of water that the residual liquid shall have exactly the composition H^2PO^4 ; the acid then crystallises on cooling.

In the purest so-called glacial phosphoric acid of commerce, Brescius (*Zeitschr. anal. Chem.* vi. 187) found 15.3 p. c. soda. He finds that really pure phosphoric acid forms only a soft glutinous mass.

The following table of the relations between the specific gravity and strength of aqueous phosphoric acid (prepared by oxidising amorphous phosphorus with nitric acid) is given by J. Watts (*Chem. News*, xii. 160):

Spec. Grav.	p. c. P^2O^3	Spec. Grav.	p. c. P^2O^3	Spec. Grav.	p. c. P^2O^3	Spec. Grav.	p. c. P^2O^3
1.508	49.60	1.369	39.21	1.236	27.30	1.095	12.18

Estimation of Phosphoric Acid.—1. The conditions under which phosphoric acid is most completely precipitated by *ammonium molybdate* have been examined by Fresenius (*Zeitschr. anal. Chem.* iv. 151): α . The estimation of phosphoric acid by precipitation with ammonium molybdate is in itself an exact method.— β . Nitric acid, even if present in very large excess, does not interfere with its accuracy.— γ . Hydrochloric acid, if present in somewhat considerable quantity, prevents the precipitation wholly or partially; when its quantity is reduced to about 3.3 p. c. of the liquid, the results, though still too low, begin to approach the truth.— δ . If a large quantity of nitric acid is also present, a somewhat considerable quantity of hydrochloric acid is still more prejudicial, 3.3 p. c. of it in that case completely preventing the precipitation.— ϵ . Sulphuric acid, ferric chloride, and aluminium chloride, even in considerable quantity, do not interfere with the precipitation.— ζ . In presence of a large quantity of sal-ammoniac, the results are somewhat too low; they also become less exact as the solution is more diluted with water.

2. According to E. Fleischer (*Zeitschr. anal. Chem.* vi. 28), aluminium phosphate, like aluminium hydrate, is slightly soluble in ammonia, so that on mixing the solution of a phosphate with a slight excess of an aluminium salt, and then supersaturating with ammonia, part of the phosphoric acid remains in solution. But in neutral solutions, or in presence of a slight excess of acetic acid, phosphoric acid is completely precipitated by aluminium salts, if not added in great excess, the precipitate having the composition $Al_2O_3 \cdot P_2O_5$. Phosphoric acid may be estimated volumetrically in a solution acidulated with acetic acid by means of a one-tenth normal solution of potash-alum (containing 5.15 grm. alumina in a litre), the end of the precipitation being indicated by adding an alcoholic solution of brazilin, which is coloured distinctly blue by aluminium acetate, even in very dilute solution (Fleischer, *Zeitschr. anal. Chem.* iv. 355; *Jahresb.* 1865, p. 707; 1867, p. 844).

According to Schweikert (*Jahresb.* 1867, p. 847), phosphoric acid cannot be completely separated from zinc oxide by fusion with sodium carbonate, since part of the phosphoric acid remains with the zinc, and part of the latter remains dissolved as sodium zincate.

Schloesing (*Compt. rend.* lxi. 1043; *Zeitschr. f. Chem.* [2] iv. 567) estimates phosphoric acid in phosphates by converting them into iron phosphide. This is effected by mixing the phosphate with an iron silicate,* charcoal, and, if the phosphate does not contain excess of base, also with metallic iron. This mixture is ignited in a charcoal-lined crucible by means of a powerful gas-blowpipe; the fused mass is pulverised; and the metallic iron phosphide separated from the granules is heated in a glass tube through which a stream of chlorine is passed. The phosphorus then passes over as trichloride, which is received in water, and the resulting phosphorous acid is oxidised by nitric acid to phosphoric acid, which is estimated by the ordinary methods.

On the estimation of phosphoric acid in phosphorite, see Fresenius (*Zeitschr. anal. Chem.* vi. 403; *Jahresb.* 1867, p. 835); in superphosphate, coprolites, plant-ashes, soils, manures, &c., see G. Jones (*Chem. News*, xii. 13); W. Arnot (*ibid.* xi. 49); H. Warrington jun. (*ibid.* xii. 209); Fresenius (*Zeitschr. anal. Chem.* vii. 304; *Jahresb.* 1868, p. 858); Schloesing (*Zeitschr. f. Chem.* [2] v. 156); De Gasparin (*Compt. rend.* lxxviii. 1176; *Zeitschr. f. Chem.* [2] v. 444).

ORTHOPHOSPHATES.—On the reactions of *tricalcic phosphate* with calcium chloride and sulphuric acid, see Piccard (*Zeitschr. f. Chem.* [2] ii. 545; iii. 187; *Jahresb.* 1866, p. 168; 1867, p. 909).

Cupric Salts.—The precipitate formed on adding 2 mol. ordinary sodium phosphate to a dilute solution of 3 mol. cupric sulphate has, when air-dried, the composition $Cu^*H(PO_4)^3 + 5H_2O$. Rammelsberg (*Pogg. Ann.* lxxviii. 388), probably by drying it at a higher temperature, obtained it with 3 mol. water. When this precipitate is boiled with very dilute ammonia, small dark blue crystals, sparingly soluble in water and alcohol, separate on cooling. By boiling the same precipitate with ammonia, placing upon this liquid a layer of alcoholic solution of ammonia, leaving it for several weeks, and promoting the diffusion by frequent gentle agitation, sky-blue crystals separate, consisting of *ammonio-cupric phosphate*, $(NH_4^*)^{Cu^{**}}(PO_4)^3 + 7H_2O$. These crystals are monoclinic prisms with oblique end-faces inclined 65° to the principal axis. They dissolve easily in cold water, smell strongly of ammonia, and give it up for the most part even at ordinary temperatures, crumbling to a bluish-white powder (Metzner, *Ann. Ch. Pharm.* cxlix. 66; *Zeitschr. f. Chem.* [2] v. 250).

* The iron silicate is prepared by fusing together 28 pts. iron filings, 80 pts. ferric oxide, and 48 pts. pure sand, separating the fused mass from the excess of iron, and pulverising.

Trithallious Phosphate, $\text{Th}^3(\text{PO}_4)$, separates in the crystalline form, even from very dilute neutral solutions of thallious salts, on addition of sodium phosphate and a drop of ammonia, but only when the solution is free from ammoniacal salts, in which it is very soluble (Carstanjen, *Jahresb.* 1867, p. 280).

Zinc Salts.—*Zinc-ammonium phosphate*, $\text{Zn}(\text{NH}_4^+)(\text{PO}_4) + \text{H}_2\text{O}$. When a solution of 64 grms. zinc sulphate and 100 grms. of aqueous phosphoric acid (strength 16 p. c.) in a large quantity of water is mixed with sufficient ammonia to redissolve the precipitate at first produced, and the liquid is left to itself in a shallow basin, the double salt separates as the ammonia evaporates, in closely adhering crusts composed of microscopic rectangular tables. A very similar salt is produced by slowly evaporating a strongly ammoniacal solution of sodium phosphate and zinc phosphate, but it always contains sodium. A moderately dilute solution of 64 grms. zinc sulphate and 100 grms. of 16 p. c. phosphoric acid exposed for some weeks in a covered basin to a winter temperature, deposits indistinct microscopic crystals, having when air-dried the composition $3\text{P}^2\text{O}_5 \cdot 4(\text{NH}_4^+)\text{O} \cdot 6\text{ZnO}$ or $\frac{6(\text{PO}_4)^{3-}}{(\text{NH}_4^+)\text{Zn}^{2+}} \text{O}^{19}$ (Hointz, *Zeitschr. f. Chem.* [2] iv. 16; see also Schweikert, *ibid.* 306). *Zinc-sodium phosphate*, ZnNaPO_4 , is produced, by melting microcosmic salt with zinc oxide in the proportions required by the formula, as a transparent colourless mass, which becomes enamel-white on cooling, is not altered by exposure to the air, does not take up water when immersed in it, does not give up soda to water, either cold or boiling, and is insoluble in both (Scheffer, *ibid.* iv. 288).

PYROPHOSPHATES. $\text{M}^2\text{P}^2\text{O}_7$ or $\text{M}^2\text{P}^2\text{O}_7$ or $\text{M}^2\text{P}^2\text{O}_7$ (Gladstone, *Chem. Soc. J.* [2] v. 435).—These salts are produced, not only by the action of heat on the orthophosphates, but likewise by treating phosphoric anhydride with a caustic alkali in alcoholic solution:

also by decomposing phosphorus oxychloride with a moderately concentrated solution of potash or ammonia:

By the action of anhydrous potassium oxide or ammonia sesquicarbonate on the oxychloride, a metaphosphate appears to be produced:

The white precipitate formed on adding ferric chloride to a solution of sodium pyrophosphate continues to redissolve till $\frac{1}{2}$ mol. ferric chloride, Fe^3Cl_3 , has been added to 1 mol. of the pyrophosphate $\text{Na}^2\text{P}^2\text{O}_7$. On further addition of the ferric salt, the precipitate becomes permanent, and when $\frac{2}{3}$ mol. has been added, the precipitation is complete, the precipitate redissolving however in a large excess of ferric chloride. This salt has the composition $(\text{Fe}^3)_2\text{P}^2\text{O}_7 + 9\text{H}_2\text{O}$, previously determined by Schwarzenberg (iv. 565). The soluble *sodio-ferric salt* appears to have the composition $\text{Fe}^3\text{Na}^2\text{P}^2\text{O}_7$, but is difficult to obtain pure. *Cupric salts* form in like manner with sodium pyrophosphate a green precipitate of the salt $\text{Cu}^2\text{P}^2\text{O}_7 + 2\text{H}_2\text{O}$, soluble with deep blue colour in excess of the sodium salt. The *ferrous, zinc, mercurous, lead, and silver salts* are likewise soluble in excess of the sodium salt, the *mercuric and chromic salts* insoluble. The normal pyrophosphates of the heavy metals are not altered by boiling with water or neutral saline solutions; they are soluble in dilute acids, and are at first precipitated from their solution in sodium pyrophosphate by sulphuric acid, but are redissolved by an excess of it. Some of them (the ferrous, ferric, cupric, and zinc salts, but not the lead, mercurous, or chromic salts) are precipitated from this solution containing the smallest possible quantity of free acid, by heat, with their original composition but with altered properties, being then soluble in ammonia, but not in sodium pyrophosphate, dilute sulphuric acid, or the original metallic salt (chloride, sulphate, &c.). Gladstone regards these abnormal pyrophosphates as allotropic modifications, which do not appear to exist in free pyrophosphoric acid or in the pyrophosphates of the alkali-metals, inasmuch as the abnormal cupric salt decomposed by hydrogen sulphide yields ordinary pyrophosphoric acid, and the abnormal ferric salt decomposed by caustic potash yields the ordinary potassium salt. The reaction of the ferric salt may be used for the detection of pyrophosphoric acid, namely by adding a few drops of ferric chloride to the solution of the salt, either neutral or prepared with the smallest possible quantity of cold sulphuric acid, redissolving the resulting precipitate in the smallest possible quantity of sulphuric acid, and heating the liquid to the boiling point, whereupon, if pyrophosphoric acid is present, a white flocculent or gelatinous precipitate is formed.

Pyrophosphoric acid may be distinguished from ortho- and meta-phosphoric acids by means of a solution of *leuco-cobaltic chloride*, which produces in solutions of alkaline pyrophosphates a reddish-yellow precipitate, immediately in moderately dilute solutions, only on agitation in case of great dilution (C. D. Braun, *Zeitschr. anal. Chem.* iii. 468).

PHOTENE. Fritzsche's name for pure anthracene (p. 176).

PHOTERYTHRINE. See the next article.

PHOTOCYANINE. A blue colouring matter produced by the action of oxidising agents in sunshine on cyanine or chinoline-blue (p. 430). It is most abundantly produced by agitating a mixture of 10 pts. concentrated alcoholic solution of cyanine and 100 pts. water at ordinary temperatures with 3 or 4 pts. lead dioxide, till it is decolorised, exposing the clear filtered liquid to the sun till it has acquired a deep blue colour, filtering again, exposing the filtrate to sunshine, and repeating this treatment five or six times. The presence of a small quantity of acid or alkali interferes with the formation of photocyanine. This substance is gradually bleached by ozone; by exposure to light it is decomposed more quickly than cyanine, and finally converted into soluble red photerythrine, or in absence of oxygen into an analogous brown-red colouring matter. Photocyanine is likewise converted into photerythrine by repeatedly treating its alcoholic solution with aqueous chlorine, bromine, or iodine, and then with reducing agents, or by exposing it to sunshine or even to diffused daylight. The solution of photerythrine has a colombo-red colour, not altered by dilute alkalis, but changed to violet by dilute acids. It is likewise decolorised by ozone, chlorine-water, &c., and then reddened again by sunshine (not by reducing agents) with continually diminished intensity of colour, till the whole of the colouring matter is destroyed. The soluble colouring matter produced from photocyanine by the action of sunlight in absence of oxygen exhibits similar reactions (Schönbein, *Ann. Ch. Phys.* [4] vii. 462; *Jahresb.* 1865, p. 424).

PHRAGMITES. The ash of different organs of the common reed (*Phragmites communis*) has been analysed by J. Fittbogen (*Jahresb.* 1865, p. 639).

PHTHALIC ACID. $C^6H^4O^4 = C^6H^2 \begin{cases} COOH \\ COOH \end{cases}$ *Monocarbohenzoic Acid. Di-carbohenzoic Acid.*—This bibasic acid, derived from benzene by substitution of 2 at. carboxyl for 2 at. hydrogen, is susceptible of three modifications, according to the relative positions of the two carboxyl-groups; namely:

Orthophthalic	Metaphthalic	Paraphthalic
1:2	1:3	1:4

The first of these is the phthalic acid described in vol. iv. p. 628, as produced by oxidation of naphthalene, alizarin, purpurin, and munjistin; the second, also called isophthalic acid, is formed by oxidation of meta-xylene or iso-xylene (p. 293); the third is terephthalic acid, produced by oxidation of turpentine oil, cuminic acid, cuminic aldehyde, xylene, and other aromatic hydrocarbons (v. 724).

1. *Orthophthalic*, or simply *Phthalic acid*, is also produced: α. Together with benzoic acid, formic acid, and carbon dioxide, by oxidising benzene with manganese dioxide and sulphuric acid, its formation being due to the combination of benzoic acid with formic acid, and simultaneous oxidation:

(Carius, *Zeitschr. f. Chem.* [2] iv. 705).

β. Together with carbon dioxide, by oxidising naphthalene with manganese dioxide and sulphuric acid; and together with dinaphthyl and a brown resinous body, by treating naphthalene with potassium dichromate and sulphuric acid (Lössen, *Ann. Ch. Pharm.* cxliv. 71; see page 844).—γ. Together with carbon dioxide, and several additive and substitution products, by the action of chlorous acid on naphthalene (Hermann, *Zeitschr. f. Chem.* [2] iv. 551; see page 844).

Phthalic acid crystallises from aqueous solution in shining monoclinic crystals, and by slow evaporation in very large, prismatic, radially united forms, with rounded summits; by cooling of the hot solution in small tables (Carius). According to Scheibler (*Zeitschr. f. Chem.* [2] iv. 719), the crystals are rhombic prisms, exhibiting the combination $\infty P. oP. \infty P\infty. P\infty$. It melts at 170° – 180° (Carius), at 184° (Lössen).

Phthalic acid neutralised with sodium carbonate and treated with sodium-amalgam, is converted into hydrophthalic acid, $C^6H^4O^4$ (Graebe & Born; *vid. inf.*). Heated with zinc-dust, it is reduced to benzoic aldehyde (Baeyer, *Jahresb.* 1866, p. 573).

Heated with 80 pts. saturated *hydriodic acid*, it yields heptane, C^7H^{16} , and a small quantity of octane, C^8H^{18} :

Terephthalic acid treated in a similar manner yields only heptane (Berthelot).

Metallic Phthalates.—A solution of phthalic acid half neutralised with baryta-water and evaporated, yields rhombic prisms of the *acid barium salt*, $(C^8H^4O^4)^2Ba$. This salt dissolves in hot water, and gives off at 160° – 200° such a quantity of phthalic acid that the residue has nearly the composition $(C^8H^4O^4)^2Ba \cdot H^2$. The same salt is obtained in crystalline crusts when a solution of the acid neutralised with baryta-water is left to evaporate. The *neutral calcium salt*, $C^8H^4O^4Ca + H^2O$, is obtained by spontaneous evaporation in shining rhombic prisms which give off their water at 160° . The *cupric salt*, $C^8H^4O^4Cu + H^2O$, prepared by adding cupric sulphate to phthalic acid neutralised with baryta-water, is easily soluble in hot water, and crystallises in shining rhombic prisms, which give off their water at 160° (Hermann, *Ann. Ch. Pharm.* cli. 78).

Ethyl Phthalate, $C^8H^{10}O^4$, $(C^2H^5)^2$, may be obtained by passing hydrochloric acid gas into an alcoholic solution of phthalic acid; when purified it is a colourless inodorous oil, boiling at 288° (corr. 295°) (Graebe a. Born, *Jahresh.* 1866, p. 411).

On *Chlorophthalic* and *Nitrophthalic acid*, see Faust (*Zeitschr. f. Chem.* [2] v. 107).

2. **Metaphthalic** or **Isophthalic acid** is produced by the oxidising action of potassium dichromate and sulphuric acid on meta-xylene (p. 293), and separates from the filtered solution in slender needles an inch long, which melt above 300° , and volatilise without blackening. Its crystalline character distinguishes it from terephthalic acid, which is an amorphous powder. The barium and calcium salts of metaphthalic acid form long needle-shaped crystals, very soluble in water (Fittig a. Velguth, *Zeitschr. f. Chem.* [2] iii. 526. Fittig, *ibid.* v. 20). Metaphthalic acid is also produced by the action of sulphuric acid on hydropyrene and hydropyromellitic acids (Bayer, p. 812).

3. **Paraphthalic** or **Terephthalic acid** is produced by oxidation of several hydrocarbons (v. 725), and in particular of paraxylene or methyl-toluene by chromic acid mixture (Fittig, *loc. cit.*); in like manner from diethyl-benzene:

(Fittig a. König, *Jahresh.* 1867, p. 610); and, together with acetic acid, by the action of chromic acid on amyl-toluene:

(Bigot a. Fittig, *ibid.* 668). It is also formed, together with phthalic acid, in the oxidation of benzene by manganese dioxide and dilute sulphuric acid (A. E. Oudemans jun., *Zeitschr. f. Chem.* [2] v. 84); by the action of strong potash-ley at the boiling heat on phenylene cyanide: $C^6H^4(CN)^2 + 4H^2O = 2NH^3 + C^8H^4(CO^2H)^2$ (Ireland, *ibid.* 165); and in very small quantity, together with metaphthalic acid, by the action of sulphuric acid on hydropyromellitic acid (Bayer).

Terephthalic acid heated with 80 pts. of saturated aqueous *hydriodic acid* yields heptane as sole product (p. 696).

On the crystallisation of ethyl terephthalate, see Oudemans (*loc. cit.*).

Hydrophthalic Acid. $C^8H^8O^4$ (Graebe a. Born, *Ann. Ch. Pharm.* cxlii. 330).—Produced by the action of nascent hydrogen upon phthalic acid. A solution of 1 pt. phthalic acid and 1 pt. crystallised sodium carbonate in 8 pts. of cold water is treated in the cold with sodium-amalgam till (in 8 to 14 days) the precipitate formed in a sample of the liquid dissolves in acetic acid. The brown liquid is then neutralised with hydrochloric acid, filtered to separate a brown substance, and the hydrophthalic acid is separated from the filtrate by further addition of hydrochloric acid.

Hydrophthalic acid purified by recrystallisation, with addition of animal charcoal, forms hard tabular monoclinic prisms (with angles of nearly 100° and 80°), cleaving parallel to the end-face. 100 pts. water dissolve 0.98 pt. of the acid at ordinary temperatures, 7.3 pts. at 100° . It is moderately soluble in alcohol, sparingly in ether; the solutions have a strong acid reaction, and decompose carbonates. *Calcium chloride* forms in concentrated solutions of the acid, especially when warm, a precipitate easily soluble in acids; *ferric chloride* forms with solutions of hydrophthalates a brown, *cupric sulphate* a green, *lead acetate*, neutral or basic, a white precipitate;

the lead precipitate is soluble in acetic acid as well as in excess of the precipitant. *Mercurous salts* form white precipitates, becoming grey at the boiling heat; *mercuric chloride* yields on boiling a precipitate of calomel.

Hydrophthalic acid is bibasic, forming acid and neutral salts, the former crystallising the more easily. The easily soluble *sodium salt* forms spherical groups of shining laminae. The *neutral barium salt*, $C^6H^4O^4Ba$, separates on evaporation in nacreous crusts, easily soluble in warm, less soluble in cold water. The *acid barium salt*, $(C^6H^3O^4)^2Ba + H^2O$, forms stellate groups of crystals, easily soluble in water, sparingly in alcohol, becoming anhydrous at $120^\circ-130^\circ$. The *neutral calcium salt*, $C^6H^4O^4Ca$, and the acid salt, $(C^6H^3O^4)^2Ca$, are slightly soluble in water, and crystallise indistinctly. The *lead salt*, $C^6H^4O^4Pb$, is a crystalline powder nearly insoluble in water, easily soluble in dilute acetic acid. The *silver salt* is a white precipitate, moderately soluble in water, becoming black on boiling, and depositing silver, especially in presence of ammonia.

Decompositions.—1. Hydrophthalic acid heated above 200° gives off water and melts to a yellow liquid, which decomposes partially at a higher temperature, yielding a yellow oily solidifying distillate, from which by recrystallisation from alcohol, phthalic anhydride, $C^8H^4O^3$, is obtained.—2. Heated with *soda-lime* it is resolved into benzene, hydrogen, and carbon dioxide:

3. With *phosphorus pentachloride*, it yields benzoyl chloride, carbon monoxide, hydrochloric acid, and phosphorus oxychloride:

4. Heated with strong *sulphuric acid*, it yields phthalic acid, benzoic acid, and carbon monoxide:

and

5. A solution of hydrophthalic acid heated with a slight excess of *bromine* yields benzoic acid, hydrobromic acid, and carbon dioxide (with a small quantity of phthalic acid):

6. Fused with *potassium hydrate*, it yields benzoic acid, together with hydrogen and carbon dioxide:

7. By oxidation with dilute *nitric acid* or with *chromic acid*, it is converted into benzoic and phthalic acids.—8. The alcoholic solution of hydrophthalic acid treated with *hydrochloric acid gas*, yields, not hydrophthalate, but benzoate of ethyl, perhaps together with formate, according to the equation:

Hydroterephthalic acid, $C^8H^4O^4$, is formed by treating terephthalic acid in moderately soluble concentrated alkaline solution with sodium-amalgam for several days, and separates, on neutralising with hydrochloric acid, as a white flocculent precipitate, quite insoluble in water, and reducing ammoniacal silver solution at the boiling heat (R. Mohs, *Zeitschr. f. Chem.* [2] iii. 68).

PHTHALIC ALDEHYDE, $C^8H^4O^2$, is formed by the action of zinc and hydrochloric acid on phthalic chloride. When dissolved out by ether and purified, it forms a white slightly aromatic substance, melting at 65° , easily soluble in alcohol and ether, slightly soluble in cold, more abundantly in hot water, and crystallising therefrom in small rhombic tables. The warm aqueous solution solidifies with sodium bisulphite to a mass of silky needles (Kolbe u. Wischin, *Chem. Soc. J.* [2] iv. 339).

Phthalic aldehyde is also the chief product formed by the action of magnesium on a solution of phthalic chloride in glacial acetic acid. It volatilises at 180° with vapour of water, and exhibits remarkable stability, perhaps arising from the union of each of its oxygen-atoms with two atoms of carbon, as represented by the formula

PHTHALIC ANHYDRIDE, $C^8H^4O^3$, is produced in the decomposition of hydrophthalic acid by heat (p. 943). It melts at 128° (Lossen; Carius; Hermann); at 129° (Graebe a. Born); the melting point 105° given by Laurent (iv. 631) is much too low; boils at 276° (Lossen).

PHTHALIC CHLORIDE, $C^8H^4O^2Cl^2$, produced by the action of phosphorus pentachloride on phthalic acid or anhydride (iv. 633), boils at 270° (H. Müller); at 268° , and solidifies at 0° (Wischin, *Ann. Ch. Pharm.* cxliii. 259; *Jahresb.* 1867, p. 722). It is but slowly decomposed by water or by aqueous sodium carbonate. Zinc-ethyl converts it (dissolved in benzol) into phenylene-diethyl ketone (Wischin):

Phthalic chloride dissolves in glacial acetic acid, and on heating the solution, hydrochloric acid is given off, and a crystalline body is formed, which is decomposed by water, and doubtless consists of acetophthalic anhydride:

When magnesium is added to a solution of phthalic chloride in about 20 pts. glacial acetic acid, and the resulting liquid is neutralised and agitated with ether, phthalic aldehyde is obtained as principal product, together with a small quantity of oil, volatilising easily with vapour of water, and having approximately the composition of the anhydride of phthalic alcohol, $C^8H^4\left\{\begin{smallmatrix} CH^2 \\ CH^2 \end{smallmatrix}\right\} > O$ (Baeyer, *Zeitschr. f. Chem.* [2] v. 399).

PHTHALOSULPHURIC ACID, $C^8H^4SO^7$, analogous to succinyl-sulphuric acid, is formed, according to O. Loew (*Ann. Ch. Pharm.* cxliii. 257), by heating phthalic acid to 100° – 105° for some time with excess of sulphuric anhydride, and leaving the product exposed to moist air. It solidifies to a crystalline mass when evaporated in a vacuum over sulphuric acid, but its salts are uncrystallisable. Their aqueous solutions, as well as that of the acid, are decomposed by boiling or by gradual evaporation, with liberation of sulphuric acid. The barium salt contains $C^8H^4SO^7Ba$.

PHYLLÆSCITANNIN. $C^{26}H^{24}O^{13}.H^2O$.—A tannin existing in the small leaflets of the horse chestnut, as long as they remain enclosed in the buds (Rochleder, *Jahresb.* 1866, p. 694).

PHYLLOCYANIC ACID and **PHYLLOXANTHIN** (iv. 633).—According to later experiments by Frémy (*Bull. Soc. Chim.* [2] v. 464; *Jahresb.* 1865, p. 585), it appears that pure chlorophyll is resolved into these two bodies by boiling with baryta-water, both separating in the insoluble form, the former as barium salt. On treating the precipitate with alcohol, the phylloxanthin dissolves, whilst the insoluble barium phyllocyanate decomposed by sulphuric acid yields phyllocyanic acid soluble in alcohol and ether.

PHYSOSTIGMINE. Further details respecting the preparation and properties of this base, the poisonous principle of the Calabar bean, have been given by Hesse (*Ann. Ch. Pharm.* cxli. 82; *Jahresb.* 1867, p. 528). Its composition is $C^{13}H^{21}N^2O^2$. Potassio-mercuric iodide throws down from its salts a white easily fusible precipitate of the double salt, $C^{13}H^{21}N^2O^2.HI.HgI^2$. Physostigmine throws down ferric oxide from a neutral solution of ferric chloride; forms a kermes-coloured precipitate with a solution of iodine in potassium iodide; and is precipitated by tannic acid, mercuric chloride, and auric chloride, but not by platinic chloride.

PICOLINE, C^6H^5N , is produced by the distillation of acrolein-ammonia. This reaction explains the formation of picoline in the dry distillation of animal substances. The fats yield acrolein, and this compound, in contact with ammonia at a high temperature, yields first acrolein-ammonia, C^6H^5NO , and then picoline:

and

(Baeyer, *Zeitschr. f. Chem.* [2] v. 570).

PICRAMIC ACID. } See AMIDOPHENOLS (p. 916).

PICRAMINE. }

PICRIC ACID. See TRINITROPHENOL (p. 911).

PICROERYTHRIN. $C^{12}H^{16}O^7$ (iv. 641).—This body is obtained with peculiar facility in the pure state by boiling erythrin for several hours with amyl alcohol:

When the reaction is complete, part of the alcohol is distilled off, and the remaining liquid is heated over the water-bath, whereupon amyl orsellinate separates as an oily layer, while the picroerythrin crystallises from the filtered liquid at about 40° in white silky prisms consisting of $C^{12}H^{16}O^7 \cdot 3H^2O$ (Hesse, *Jahresb.* 1866, p. 659).

PIMARIC ACID. Maly (*Ann. Ch. Pharm.* cxxix. 94; cxxxi. 253; *Zeitschr. f. Chem.* [2] v. 304) regards this acid as identical with his abietic acid, $C^{14}H^{18}O^3$; but Duvernoy (*Ann. Ch. Pharm.* cxlviii. 143; *Zeitschr.* [2] v. 303), working under Strecker's direction, has confirmed the results obtained by Laurent and by Siewert (iv. 615), according to which pimaric acid is isomeric with sylvic acid, and has the composition $C^{20}H^{30}O^4$.

Pimaric acid prepared from French galipot by washing with cold dilute alcohol till that liquid no longer becomes yellow, and crystallising from boiling alcohol, forms hard granular crusts, appearing under the microscope to be made up of well-defined rectangular crystals; it is insoluble in water, slightly soluble in cold, freely in hot alcohol and ether. It melts at 149° , and boils at a temperature above 320° (Duvernoy); according to Laurent, it melts at 125° , according to Sievert at 155° .

Sodium pimarate, $C^{20}H^{28}O^2Na + 4H^2O$, separates from a solution of the acid in excess of very dilute soda-ley, in shining crystals, and is obtained by recrystallisation from alcohol in nacreous laminae. It is nearly insoluble in cold water, easily soluble in hot water, also in alcohol and ether; a large quantity of water decomposes it into an acid salt and free alkali. It gives off its water at 100° , and is not decomposed at 140° . An acid potassium salt, $C^{20}H^{26}O^2K \cdot 2C^{20}H^{30}O^2$, separates in the crystalline form when pimaric acid is added to hot alcoholic potash till the alkaline reaction is nearly neutralised; it dissolves sparingly in water, easily in alcohol, and melts at 121° . The neutral potassium salt was obtained in very small quantity only. The acid ammonium salt, $C^{20}H^{28}O^2(NH^4)$, $C^{20}H^{30}O^2$, separates from a solution of the acid in aqueous ammonia, in long silky needles, soluble in water, but decomposed by a large quantity of water. The magnesium, calcium, barium, strontium, and lead salts may be easily prepared from the sodium salt and purified by alcohol and ether. The silver salt, $C^{20}H^{28}O^2Ag$, quickly turns red on exposure to light. Laurent & Sievert describe all these salts as uncrystalline; Laurent indeed indicates the uncrystallisability of the lead salt as affording a distinction between pimaric and sylvic acids; Duvernoy, however, obtained the lead salt crystallised from ether.

When hydrochloric acid gas is passed into an alcoholic solution of pimaric acid, a modified pimaric acid is deposited, as a crystalline precipitate, which forms with ammonia, not a crystalline, but a gelatinous salt. The free acid melts at 143° , and crystallises from alcohol in microscopic truncated triangular plates. This modification, as well as the former, turns the plane of polarisation to the left.

Pimaric acid yields, by distillation, a yellow, transparent, brittle, acid resin, the alcoholic solution of which does not deposit crystals. The ammonium salt of this acid is gelatinous when first prepared, but changes in a few days into needle-shaped crystals. The free acid melts at 129° , and is not therefore unaltered pimaric acid, as stated by Sievert. Sylvic acid prepared from colophony melts at 129° , and likewise yields a gelatinous ammonium salt (Duvernoy; see also Strecker, *Ann. Ch. Pharm.* cl. 131).

PIMELIC ACID. $C^{11}H^{12}O^4$, is formed, together with other products, by fusing camphoric acid with potash (Hlasiwetz & Grabowski). See CAMPHORIC ACID (p. 389).

PINACONE. $C^8H^{14}O^2$.—The following additional observations on this body have been made by Friedel (*Zeitschr. f. Chem.* [2] v. 485). Pinacone is not susceptible, as supposed by Linnemann (iv. 648), of two modifications, one liquid and the other solid, the supposed liquid modification being merely in a state of surfusion, like water cooled under certain circumstances below 0° . In fact, pinacone, when distilled in an oil-bath, may remain fluid for a long time after cooling, but rapidly crystallises, with rise of temperature, on rubbing the sides of the vessel with a glass rod.

Pinacone exhibits the chemical relations of a glycol. On treating it in the cold with hydrochloric acid gas, a chlorinated product is obtained which is decomposed by distillation, and when treated with potash yields pinacolin, $C^8H^{12}O$ (iv. 647). This latter product is likewise formed by treating pinacone with glacial acetic acid. Pinacone is not converted into pinacolin by merely heating it strongly in a sealed tube. Phosphorus pentachloride acts strongly on pinacone, converting it, with evolution

Sup.

of hydrochloric acid, into a chloride, which appears to have the composition of hexylene chloride, $C^6H^{12}Cl^2$, and boils, apparently with decomposition, at about 160° . Treated with sodium this chloride yields an oily liquid boiling between 60° and 70° , and apparently consisting of hexylene. Friedel represents pinacone by the formula

that is to say, as tetramethylated ethyl-glycol, and the hexylene obtained from it as tetramethylated ethylene.

PIPERIC ACID. $C^{12}H^{10}O^4 = C^{11}H^9O^2.CO^2H$ (Fittig a. Mielck, *Ann. Ch. Pharm.* clii. 25; *Zeitschr. f. Chem.* [2] v. 326).—This acid, prepared according to the method of v. Babo a. Keller (iv. 653) by heating piperine with alcoholic potash, and purified by separation from its potassium salt and recrystallisation, melts in the first instance at 216° – 217° ; but after being once fused, it melts constantly at 212° – 213° , not at 150° as stated by v. Babo a. Keller. When heated a few degrees above its melting point, it sublimes with partial decomposition in slender needles. It may be heated with pure water to 230° for days without sensible decomposition, but between 235° and 245° it decomposes completely into carbon dioxide and a mixture of non-acid resinous bodies. Very weak hydrochloric acid appears to produce the same decomposition even below 160° , strong hydrochloric acid at 100° . Piperic acid heated with quick lime decomposes almost completely into water, carbon dioxide, and free carbon, with only a trace of an oil very much like phenol.

Potassium piperate heated with ethyl iodide, potash, and alcohol, yields only ethylic piperate, not a trace of ethylic ethyl-piperate. Piperic acid is not decomposed by acetyl chloride, even when heated therewith in sealed tubes, and when heated with hydriodic acid, it yields only a trace of a volatile iodine compound: hence it appears that the two oxygen-atoms in piperic acid not included in the carboxyl group are not present as HO, or as $CH^{\circ}O$, $C^2H^{\circ}O$, &c.

Piperic acid is oxidised by chromic acid mixture, even at ordinary temperatures, quickly and completely at a gentle heat, the only products being water and carbon dioxide. Mixed in neutral solution with aqueous potassium permanganate, it instantly reduces that compound, and is oxidised to piperonal, $C^8H^6O^3$ (p. 947), together with oxalic acid, carbon dioxide, and water:

A small quantity of the piperonal is further oxidised to piperonylic acid. Dilute nitric acid acts very strongly on piperic acid, producing a red, non-acid, amorphous body, sparingly soluble in the ordinary solvents, and completely dissolved by prolonged boiling with nitric acid, yielding a large quantity of oxalic acid. The solution filtered from the red substance contains piperonal or a nitro-derivative of it, which crystallises well and melts at 138° – 139° .

When piperic acid is triturated with a small quantity of water, and with bromine gradually added to it, the bromine is slowly taken up; and on washing the product with water and dissolving it in hot alcohol, unaltered piperic acid crystallises out, and the mother-liquor leaves on evaporation a non-acid resinous body, which when distilled with aqueous sodium carbonate, yields a colourless distillate of monobromopiperonal, $C^8H^6BrO^3$, which crystallises in the condensing-tube in needles. This body does not exist ready-formed in the resin, but is produced from it by the action of the sodium carbonate, for the resin does not yield it by distillation with pure water. The nature of the constituent of the resin from which the bromopiperonal is formed has not been exactly made out; but it appears to be a body having the composition $C^8H^6Br^2O^4$, which may be obtained in the separate state by agitating 1 mol. piperic acid suspended in water with an ethereal solution of 4 mol. bromine, whereupon the piperic acid disappears, and a heavy red ethereal liquid gradually settles to the bottom; on agitating the whole with solution of sodium carbonate, the colour disappears, the ether rises to the top, and numerous small colourless nacreous laminae separate, the composition of which may be represented by the formula $C^8H^6Br^2O^4$. From this compound the bromopiperonal may be found according to the equation:

Another substance remains dissolved in the ether, and may be obtained, by evaporation and repeated crystallisation from alcohol, in colourless prisms whose composition

may be represented empirically by either of the formulae, $C^{12}H^8Br^2O^4$ or $C^{12}H^{10}Br^2O^4$. This body gently heated with strong potash-ley yields piperonal.

Hydropiperic acid, $C^{12}H^{12}O^4$, reacts with oxidising agents and with bromine very much like piperic acid. Treated in neutral solution with potassium permanganate, it likewise yields piperonal; but the reaction is not so definite as with piperic acid; the piperonal which distils over is not quite pure; and the residue of the distillation yields with hydrochloric acid a black viscid resinous precipitate.

PIPERIDINE. $C^8H^{11}N$ (Wertheim, *Ann. Ch. Pharm.* cxxvii. 75).—This base may be prepared directly from pepper by distilling the alcoholic extract with excess of caustic potash, ultimately with addition of a little water. The nearly colourless alkaline distillate containing a small quantity of volatile oil, together with piperidine and ammonia, is saturated with sulphuric or hydrochloric acid, and evaporated to dryness; the residue is exhausted with absolute alcohol; the solution again evaporated; and the admixed pepper-oil is separated by solution in a small quantity of water, filtering through a wet filter, and repeated evaporation over the water-bath. The concentrated aqueous solution is then decomposed with caustic potash, and the oily layer of piperidine thereby separated is rectified. 28 kilogr. of pepper (white and black in equal parts) thus treated yield 350 grm. pure piperidine.

The crystalline forms of several piperidine salts have been determined by Zepharrow (*Wien. Akad. Ber.* lii. [1] 241; *Jahresh.* 1866, p. 479).

Nitrosopiperidine. $C^8H^{10}N^2O = N \begin{Bmatrix} C^8H^{10} \\ NO \end{Bmatrix}$ (Wertheim, *loc. cit.*).—When piperidine is slowly saturated with nitrous acid, a dark emerald-green liquid is formed, which, after the excess of nitrous acid has been removed by slowly passing carbon dioxide through it at 30° – 40° , changes to a wine-yellow oil having a pungently acid but aromatic odour; and on mixing this oil, first with an equal volume of water, then by drops and in a well-cooled vessel with strong potash-ley, a yellowish-red oil separates, which, by agitation with dilute hydrochloric or glacial phosphoric acid, drying over calcium chloride, and rectification at 160° , yields pure nitrosopiperidine. This compound is likewise formed, according to Bunge (*Zeitschr. f. Chem.* [2] v. 649), together with water, by distilling piperidine nitrite.

Nitrosopiperidine is a pale, wine-yellow, neutral liquid, having an unpleasant aromatic odour and burning aromatic taste. Sp. gr. 1.0659 at 15.5° . It volatilises without alteration at 160° – 180° , and boils at 240° with partial decomposition. Vapour-density 4.04 (calc. 3.94). It dissolves with moderate facility in water, much more easily in acids, especially in concentrated acids, and is precipitated therefrom by water, also in aqueous solution by common salt.

Nitrosopiperidine is reconverted by nascent hydrogen (zinc and hydrochloric acid) into piperidine, with simultaneous formation of ammonia and water:

Heated to 100° in hydrochloric acid gas, it yields piperidine hydrochloride and chloronitrous acid:

At ordinary temperatures hydrochloric acid gas is absorbed by nitrosopiperidine, forming a colourless mass probably consisting of $C^8H^{10}N^2O.HCl$. On continuing the passage of the gas, the crystalline compound melts to a syrupy liquid, the increase in weight of which corresponds to the formula $C^8H^{10}N^2O.2HCl$. Both these salts are completely decomposed by water, with separation of nitrosopiperidine. The platinum-chloride has not been obtained (Wertheim).

PIPERINE. $C^{17}H^{19}NO^3$.—A warm solution of this base in alcohol containing hydrochloric acid, mixed with the requisite quantity of a solution of iodine in potassium iodide, deposits on cooling steel-blue prisms of the compound $2C^{17}H^{19}NO^3.HI^2$ (Jørgensen, *Zeitschr. f. Chem.* [2] v. 675).

PIPERONAL. $C^8H^8O^3 = C^8H^8O^2.CHO = C^8H^8-O-CO-COH$ (Fittig a. Mielck, *Ann. Ch. Pharm.* clii. 35; *Zeitschr. f. Chem.* [2] v. 327; Remsen a. Fittig, *Zeitschr.* [2] vi. 97).—Produced by oxidation of piperic acid in neutral solution with potassium permanganate (p. 946). When an aqueous solution of potassium piperate is mixed with permanganate, each drop of the latter is almost instantly decolorised, and brown manganic hydrate is separated. The solution acquires a very pleasant odour, like that of coumarin, and yields piperonal by distillation.

Piperonal crystallises from water in colourless, transparent, highly lustrous prisms, an inch long and a line broad. It is sparingly soluble in cold water, more easily in hot water, easily in cold alcohol, and in all proportions of boiling alcohol and of

ether. It has a very agreeable odour, much like that of coumarin, melts exactly at 37° , and boils without decomposition at 263° . It has decidedly the characters of an aldehyde, forming with *acid sodium sulphite* a compound like that of benzoic aldehyde, crystallising in laminæ slightly soluble in water and in alcohol; with *alcoholic ammonia*, a basic compound very slightly soluble in water. By further oxidation or by heating with *alcoholic potash* it is converted into an acid containing an additional atom of oxygen. It is not altered by aqueous alkalis, but passes over almost undecomposed even when distilled with moderately concentrated potash- or soda-ley: hence it is not a hydroxyl-phenol. Heated with water and *sodium-amalgam*, it yields piperonyl alcohol, $C^8H^8O^3$, and two isomeric bodies, *hydropiperoin* and *iso-hydropiperoin*, $C^8H^{14}O^6$, analogous to hydrobenzoïn.

Bromopiperonal, $C^8H^7BrO^3$, produced, as above described (p. 946), by treating *pipe ric acid* with bromine, and distilling the product with sodium carbonate, is insoluble in cold, somewhat soluble in boiling water, easily soluble in hot, slightly in cold alcohol, and crystallises from alcohol in long, flexible, shining, colourless needles; melts at 129° , volatilises perceptibly at 70° , and so easily with vapour of water that narrow condensing tubes are very soon stopped up by it. Cold fuming nitric acid converts it into a well-crystallised nitro-compound. With sodium-amalgam it yields piperonal and its products of reduction.

Chlorinated Derivatives of Piperonal.—1 mol. piperonal and 1 mol. phosphorus pentachloride mixed together at ordinary temperatures produce piperonal chloride, $C^8H^5O^2 \cdot CHCl^2$, according to the equation:

This compound is liquid, boils at 230° – 240° , but decomposes for the most part on distillation, and is slowly reconverted by water at ordinary temperatures into piperonal. When 1 mol. piperonal is heated with 3 mol. PCl^3 , hydrochloric acid is evolved, phosphorus oxychloride distils over, and there remains a colourless or slightly yellow liquid, consisting of dichloropiperonal chloride, $C^8H^3Cl^2O^2 \cdot CHCl^2$; it boils at about 280° , and thickens but does not solidify at low temperatures. In contact with water or with moist air it is quickly resolved into hydrochloric acid and dichloropiperonal, $C^8H^3Cl^2O^3 = C^8H^3Cl^2O^2 \cdot COH$ or $C^8H^3Cl^2 \cdot O-CO-COH$, a solid body, insoluble in cold water, easily soluble in alcohol and in toluene, and crystallising from the latter in colourless needles. This last compound boiled with water, or heated to 100° with water in sealed tubes, gives up the whole of its chlorine as hydrochloric acid, and is converted, with elimination of carbon dioxide, into *protocatechuic aldehyde*, $C^8H^3O^3$, isomeric with oxybenzoic acid:

Nitropiperonal, $C^8H^5(NO^2)O^3$, is formed when piperonal, piperonyl alcohol, hydropiperoin, or isohydropiperoin, is warmed with nitric acid of sp. gr. 1.39. On pouring the resulting solution into water, the nitro-compound separates as a light yellow crystalline mass. It is nearly insoluble in cold water, but dissolves easily in hot water and in alcohol, and crystallises from water in long colourless needles which quickly become golden-yellow on exposure to the air. It melts at 95.5° (Remsen & Fittig).

Hydropiperoin. $C^8H^{14}O^6$.—This compound, formed by the action of nascent hydrogen on piperonal, is nearly insoluble in water even at the boiling heat, also in cold alcohol, sparingly soluble in hot alcohol, and separates therefrom on cooling in stellate groups of hard pointed crystals melting at 202° .

Isohydropiperoin, $C^8H^{14}O^6$, is also nearly insoluble in cold water, but may be recrystallised from boiling water. It dissolves easily in alcohol, and may therefore be readily separated by alcohol from hydropiperoin. It crystallises in felted groups of long soft needles which melt at first at 138° , but after being once liquefied, melt again at 135° .

Acetyl chloride converts hydropiperoin slowly, and isohydropiperoin more quickly, into hydropiperoin chloride, $C^8H^{12}O^4Cl^2$, as represented by the following equation:

This chloride is nearly insoluble in water and alcohol at ordinary temperatures. By prolonged boiling with water it is decomposed, with formation of hydrochloric acid. It becomes slightly yellow at 150°, melts at 198°, decomposes immediately after fusion, with evolution of gas, and is converted into a viscid brownish-yellow mass which does not resolidify on cooling (Remsen a. Fittig). See further, *Ann. Ch. Pharm.* clix. 129; *Chem. Soc. J.* [2] ix. 934.

PIPERONYL ALCOHOL, $C^8H^{10}O^2$, also a product of the action of sodium-amalgam on piperonal, forms colourless crystals melting at 51°. It is very sparingly soluble in water, separates therefrom as a liquid, and remains liquid for a long time in contact with water. In alcohol it dissolves in almost all proportions. It is not volatile without decomposition. With acetyl chloride it gives off hydrochloric acid, and forms a liquid acetic ether (Remsen a. Fittig).

PIPERONYLIC ACID, $C^8H^6O^4$, is formed in small quantity, as a secondary product, in the preparation of piperonal, and may be separated from the residue of the distillation by hydrochloric acid. From pure piperonal it is easily obtained by adding potassium permanganate to the aqueous solution till the odour of the piperonal disappears, then filtering, evaporating, and precipitating with hydrochloric acid. It may also be prepared, though less pure, by boiling piperonal with alcoholic potash. The acid obtained in either way may be purified by recrystallisation from alcohol and sublimation. It is nearly insoluble in cold water, sparingly soluble in boiling water, alcohol, and ether, more easily in boiling alcohol. From boiling water it crystallises in large, thick, colourless, spicular crystals, apparently monoclinic prisms with oblique end-faces. When perfectly purified by repeated sublimation, it melts exactly and without the slightest coloration at 227.5° to 228.5°. It sublimes below its melting point, and, if quite pure, without decomposition.

Piperonylic acid is monobasic, and must therefore differ in constitution from phthalic acid, with which it is isomeric. The potassium salt, $C^8H^5O^4K$, crystallises from hot alcohol in small, hard, colourless prisms; from water in small, hard, inconspicuous needles. It is easily soluble in water, moderately in boiling alcohol, sparingly in cold alcohol. The silver salt, $C^8H^5O^4Ag$, is obtained as a granular crystalline precipitate, and crystallises from hot water in long, narrow, colourless laminae permanent in the air. The barium salt, $(C^8H^5O^4)^2Ba + H^2O$, is easily soluble in hot water, and crystallises therefrom in hard shining prisms. The calcium salt, $(C^8H^5O^4)^2Ca + 3H^2O$, forms tufts of colourless silky needles or laminae, moderately soluble in cold, easily in hot water. The zinc salt forms large colourless pointed crystals sparingly soluble in cold water.

The solution of the potassium salt forms a cinnamon-coloured precipitate with ferric chloride, white with mercuric chloride and with lead nitrate. With cupric solutions in the cold it forms a bright green precipitate which, when heated in the liquid, quickly becomes light blue, almost colourless.

Piperonylic acid reacts almost exactly like piperic acid with chromic acid solution, and when distilled with excess of lime. It is also easily oxidised by dilute nitric acid, with formation of oxalic acid and carbon dioxide. By sodium-amalgam it is very slowly converted into an acid, which dissolves very easily in hot water and in ether, and exhibits the general characters of an aromatic hydroxylic acid (Fittig a. Mielch, *loc. cit.*).

When piperonylic acid is heated with dilute hydrochloric acid in sealed tubes to 160°–200°, a black mass separates, consisting almost wholly of free carbon, and the nearly colourless solution yields on evaporation protocatechuic acid or pyrocatechin, according to the temperature to which the materials have been heated. At 160°–170°, the product is almost wholly protocatechuic acid, but at 190°–200° pyrocatechin is formed, with elimination of carbon dioxide:

The quantities of these bodies obtained are, however, much below the theoretical quantities (Remsen a. Fittig, *Zeitschr. f. Chem.* [2] vi. 101) See further, *Ann. Ch. Pharm.* clix. 129; *Chem. Soc. J.* [2] ix. 936.

PLATINUM. A method of separating platinum from the allied metals, founded on its behaviour with caustic soda, is given by W. von Schneider (*Ann. Ch. Pharm. Suppl.* v. 261). Platonic chloride in aqueous solution is scarcely, if at all, reduced to platinous chloride by excess of sodium hydrate, even after prolonged boiling, whereas the higher chlorides of the other platinum metals, when similarly treated, are more or less converted (with formation of sodium chloride and hypochlorite) into lower chlorides not precipitable by sal-ammoniac. The separation may therefore be effected

as follows. The platinum ore having been exhausted with nitromuriatic acid, and the nitric acid removed by evaporation, the solution is mixed with a very large excess of soda-ley free from potash, and boiled till a small portion of the platinum tetrachloride is reduced to dichloride; a little alcohol is added to decompose sodium hypochlorite; the precipitate is redissolved in hydrochloric acid; and the solution, filtered if necessary, is mixed with a hot-saturated solution of sal-ammoniac, whereby, if the preceding conditions have been accurately observed, the platinum alone is precipitated as light yellow ammonium platinochloride. If, on the contrary, the excess of soda-solution added has not been sufficient, the precipitated platinochloride contains some of the other platinum metals, which remain behind when the platinum-sponge prepared therefrom is dissolved. The metals remaining in solution are precipitated at the boiling heat by a strip of copper-plate; the precipitated metallic powder is washed; the palladium dissolved out of it by nitric acid; and the residue, which still contains platinum, is added to the next preparation.

Döbereiner's method of purifying platinum solutions by treatment with calcium hydrate is the same in principle as that just described, the higher chlorides of all the metals of the group except platinum being thereby also reduced to lower chlorides; but it does not effect complete separation, as Schneider has shown by analysis of Russian platinum coins and platinum-sponge which had been purified by Döbereiner's method.

Platinum and iridium may be separated by the different solubilities of their sulphites. The mixed oxides of the two metals are suspended in a solution of potassium carbonate or sulphite; the liquid is saturated with sulphurous acid; and the solution (containing all the platinum as platinous sulphite, and part of the iridium as potassio-iridous sulphite) is boiled with the precipitate (iridic sulphite), the water being renewed as it evaporates, to expel the free sulphurous acid. The whole of the iridium is thereby separated; and the filtrate, evaporated, ignited, and washed, yields pure metallic platinum (Birnbaum, *Ann. Ch. Pharm.* cxxxix. 164).

Respecting the absorption or occlusion of hydrogen by platinum, see GASES, ABSORPTION OF (p. 634).

Platinisation of Metals.—A convenient liquid for this purpose is prepared by adding sodium carbonate to a solution of platinic chloride as long as carbon dioxide is thereby evolved, then a small quantity of starch-sugar, and, finally common salt, till the precipitated metal exhibits a pure white platinum colour. Small objects may be platinised by mere contact action (Böttger, *J. pr. Chem.* [2] iv. 524).

Bromides (Topfse, *Jahresh.* 1868, p. 274).—*Acid Platinic Bromide* or *Hydroplatinic Bromide*, $\text{PtBr}^4 \cdot 2\text{HBr} + 9\text{H}^2\text{O}$, is obtained, by dissolving platinum-sponge in a mixture of nitric acid and excess of hydrobromic acid, and evaporating the solution over quick lime, in transparent, crimson, very deliquescent prisms, apparently belonging to a clinometric system. They melt at 100° , giving off water, hydrobromic-acid, and bromine, and ultimately leave a solid mass of platinous bromide and undecomposed acid platinic bromide; neutral platinic bromide cannot be obtained in this way. To obtain platinous bromide, PtBr^2 , acid platinic bromide is heated to 200° till it is converted into a solid yellow mass; this, when lixiviated with water, yields the dibromide as a greenish-brown powder, insoluble in water, moderately soluble in hydrobromic acid and potassium bromide. It withstands a temperature of 240° for a short time, but is partially decomposed by prolonged heating to 200° .

Bromonitrite of Platinic Bromide, $\text{PtBr}^4 \cdot 2\text{NOBr}$, is formed when platinum is treated with a mixture of hydrobromic acid and excess of nitric acid, and separates as a dark brown metallicly shining powder, composed of microscopic cubes, deliquescent in the air with evolution of bromonitrous acid, and decomposed by water with evolution of nitrogen tetroxide.

Platinobromides.—*Ammonium platinobromide*, $2\text{NH}^4\text{Br} \cdot \text{PtBr}^4$, is obtained by precipitation as a crystalline orange-coloured powder, the solution of which in 200 pts. of water deposits the salt by spontaneous evaporation in large, shining, crimson cubo-octohedrons. The *sodium salt*, $2\text{NaBr} \cdot \text{PtBr}^4 + 6\text{H}^2\text{O}$, crystallises in irregularly developed, mostly tabular, triclinic prisms, isomorphous with the corresponding chlorine-compound. The following platinobromides have been prepared by saturating acid platinic bromide with the corresponding carbonates. The *barium and strontium salts*, $\text{M}^2\text{Br}^2 \cdot \text{PtBr}^4 + 10\text{H}^2\text{O}$, apparently isomorphous, form crimson, laminar, somewhat deliquescent crystals. The *lead salt*, $\text{PbBr}^2 \cdot \text{PtBr}^4$, forms shining red-brown granules easily soluble in a small quantity of water, partially decomposed by a larger quantity. The *cupric salt*, $\text{CuBr}^2 \cdot \text{PtBr}^4 + 8\text{H}^2\text{O}$, forms large tabular, apparently rhombic, deliquescent crystals. The *nickel salt*, $\text{NiBr}^2 \cdot \text{PtBr}^4 + 6\text{H}^2\text{O}$, crystallises in brownish-

green combinations of a rhombohedron with a prism of the second order (axes $a : c = 1 : 0.5136$; angle of terminal edges = $127^\circ 34'$), and is isomorphous with the corresponding double chloride. The platinobromides of *magnesium, manganese, zinc, and cobalt* have the general formula $M''Br^2.PtBr^4 + 12H^2O$; they are very soluble, but crystallise easily in irregularly developed rhombohedral combinations containing the same amount of water as the corresponding platinochlorides:

	Length of principal axis c of the rhombohedron ($a = 1$)	Terminal angle of rhombohedron
$MgBr^2.PtBr^4 + 12H^2O$	0.6974	$114^\circ 12'$
$MnBr^2.PtBr^4 + 12H^2O$	0.7025	$113^\circ 53'$
$ZnBr^2.PtBr^4 + 12H^2O$	0.6989	$114^\circ 6'$
$CoBr^2.PtBr^4 + 12H^2O$	0.6970	$114^\circ 10'$

The *calcium salt* has the same amount of water, and crystallises in small crimson ill-defined crystals.

Chlorides. When a solution of platonic chloride, freed from nitric acid by heating with hydrochloric acid, is evaporated over sulphuric acid and lime, large brown-red very deliquescent crystals are obtained, consisting of the *acid chloride, hydroplatinic chloride, or hydrogen platinochloride*, $H^2PtCl^6 + 6H^2O$ or $2HCl.PtCl^4 + 6H^2O$ (R. Weber, *Pogg. Ann.* cxxxi. 443).

Fuming nitric acid added to not very acid solutions of platonic chloride throws down the greater part of the platinum as a yellow precipitate, which when drained on an asbestos filter, and dried on a porous plate over sulphuric acid, forms a brownish-yellow deliquescent powder. This substance dissolves in water with evolution of nitrogen dioxide; but is decomposed by potash, with formation of nitric acid and without evolution of gas. Weber (*ibid.* 441) represents this compound by the formula $PtCl^4.2NO^3Cl + H^2O$; it is probably identical with that which Boyé and Rodgers obtained (iv. 668) by evaporating platonic chloride with nitromuriatic acid.

Platinochlorides.—Topsøe (*Jahresb.* 1868, p. 273) has prepared the following platinochlorides by adding weighed quantities of the corresponding oxides or carbonates to solution of acid platonic chloride, ($PtCl^4.2HCl + 6H^2O$), and evaporating over sulphuric acid at ordinary temperatures. The *barium salt*, $BaCl^2.PtCl^4 + 4H^2O$, crystallises in monoclinic prisms, $\infty P \infty . oP . \infty P . P$, sometimes tabular from predominance of the orthopinacoids, and having the clinodiagonal, orthodiagonal, and principal axis in the proportion of $0.948 : 1 : 1.48$, and the angle of the inclined axes = $77^\circ 40'$. The *calcium salt*, $CaCl^2.PtCl^4 + 3H^2O$, forms light yellow, warty or laminar, somewhat deliquescent crystals. The *lead salt*, $PbCl^2.PtCl^4 + 3H^2O$, crystallises in hard light yellow cubes, decomposed by a large quantity of hot water, with separation of lead chloride; according to Birnbaum, the crystals contain $4H^2O$, have an orange-red colour, effloresce over sulphuric acid, but deliquesce in the air, and dissolve easily in water and in alcohol.

The platinochlorides of the magnesium group have the general formula $M''Cl^2.PtCl^4 + 6H^2O$. They are very soluble—the cupric salt very deliquescent—but nevertheless crystallise with facility. The more or less yellow crystals are combinations of a rhombohedron of the first order with a prism, usually predominating, of the second order; sometimes they exhibit a monoclinic or even quadratic aspect. Topsøe describes the following:

	Length of axis c ($a = 1$)	Terminal angle of primary rhombohedron
$MgCl^2.PtCl^4 + 6H^2O$	0.5169	$127^\circ 17'$
$MnCl^2.PtCl^4 + 6H^2O$	0.5310	$126^\circ 10'$
$FeCl^2.PtCl^4 + 6H^2O$	0.5144	$127^\circ 30'$
$NiCl^2.PtCl^4 + 6H^2O$	0.5162	$127^\circ 22'$
$CoCl^2.PtCl^4 + 6H^2O$	0.5140	$127^\circ 32'$
$ZnCl^2.PtCl^4 + 6H^2O$	0.5169	$127^\circ 18'$
$CdCl^2.PtCl^4 + 6H^2O$	0.5235	$126^\circ 46'$
$CuCl^2.PtCl^4 + 6H^2O$	0.5219	$126^\circ 53'$

The magnesium and manganese salts crystallise in this form only above 20° ; at lower temperatures, in irregularly developed combinations of two rhombohedrons with a prism of the second order; these two salts are likewise isomorphous:

	Axis c	Terminal angle
$MgCl^2.PtCl^4 + 12H^2O$	0.7057	$113^\circ 40'$
$MnCl^2.PtCl^4 + 12H^2O$	0.7073	$113^\circ 44'$

From these results it appears that the double salts of platonic chloride are isomorphous with those of platonic bromide containing the same quantities of water, also with the double fluorides of tin, titanium, zirconium, and silicium investigated by Marignac (*Jahresh.* 1859, p. 106; 1860, p. 134), and according to experiments by Jørgensen, cited by Topsøe, with the double salts of stannic chloride.

Silver chloride dissolves abundantly in concentrated solution of platonic chloride and crystallises out unaltered; but if to a perfectly neutral solution of platonic chloride mixed with a large quantity of ammonia, there be added, immediately after mixture, an ammoniacal solution of silver nitrate, a granular microcrystalline precipitate is formed, which, when dried over sulphuric acid, has the composition $\text{Ag}^2\text{PtCl}^4 \cdot 2\text{NH}^4 + \text{H}^2\text{O}$. This compound treated with cold potash-ley gives off all its ammonia, and when boiled with sodium carbonate deposits all the silver and part of the platinum in the form of a dingy yellow precipitate, while the greater part of the platinum remains dissolved, forming a yellow solution from which, after acidulation with hydrochloric acid, the platinum may be precipitated as ammonium platinochloride. *Mercurous chloride* is decomposed by platonic chloride, with separation of mercury, and the solution yields on evaporation, first crystals of mercuric chloride, and afterwards a dark brown non-crystalline deliquescent mass (Birnbäum, *Zeitschr. f. Chem.* [2] iii. 520; *Bull. Soc. Chim.* [2] viii. 416).

Silver nitrate added to a solution of platonic chloride throws down the whole of the platinum in the form of a yellow precipitate of *argento-platinoous chloride*, $\text{AgCl} \cdot \text{PtCl}_2$, which does not blacken in sunshine, but slowly turns grey in diffused daylight. *Mercurous nitrate* forms with platonic chloride a light yellow precipitate quickly turning brown, whose proportional composition agrees with the formula $\text{PtCl}_2 \cdot 2\text{HgO} \cdot \text{Hg}^2\text{Cl}^2 + 5\text{H}^2\text{O}$; by fractional precipitation, compounds of permanent yellow colour are at length obtained. All these precipitates decompose, with separation of platinum, when heated with the liquid (platinum is also separated by precipitating from hot solutions) and dissolve in boiling nitric acid. When heated alone, they yield a sublimate of mercurous chloride, mercuric chloride, and mercuric oxide, together with water, and a residue of platinum. Platonic nitrate is not formed in the decomposition of platonic chloride by silver nitrate and mercurous nitrate (Commaillie, *Bull. Soc. Chim.* [2] vi. 262).

On the reaction of platonic chloride with sulphurous acid, see SULPHITES.

Platonic Iodochloride, PtCl_2I^2 , is formed by dissolving platinum in nitro-muriatic acid, together with the quantity of iodine necessary to form platonic iodide, evaporating over the water-bath as long as acid fumes continue to escape, and leaving the solution to cool over sulphuric acid. It then separates in large brick-red prisms, which deliquesce in the air, and melt even below 100° to a red mobile liquid, smelling of iodine chloride when continuously warmed. The aqueous solution forms with chloride of potassium or ammonium a precipitate of potassium or ammonium platino-chloride, whilst potassium or ammonium iodide remains in solution. It is coloured deep red by potassium iodide, and decomposed by iodine monochloride in the manner represented by the equation $\text{PtCl}_2\text{I}^2 + 2\text{ICl} = \text{PtCl}_4 + 2\text{I}^2$ (Kämmerer, *Ann. Ch. Pharm.* cxlviii. 329).

Diplatino-carbonyl tetrachloride, $(\text{CO})^2\text{Pt}_2\text{Cl}_4 = \text{COPtCl}_2 \cdot \text{C}^2\text{O}^2\text{PtCl}_2$ (?).—This compound is formed when a mixture of chlorine and carbon monoxide is passed over spongy platinum heated to dull redness in a glass tube; it then sublimes as a yellow powder which must be immediately enclosed in dry glass vessels. This powder appears to contain different compounds, according to the temperature and other circumstances of the preparation, inasmuch as its melting point is found to vary from 130° to 150° . It dissolves easily in warm carbon tetrachloride, and separates in shining needles on cooling. When quickly and strongly heated, it is decomposed, giving off carbon monoxide and carbon oxychloride, and leaving platinum. As it decomposes nearly at the temperature at which it volatilises, it cannot be distilled, excepting in a stream of gas. It blackens in contact with moist air, and is instantly decomposed by water, with formation of carbon monoxide and dioxide, hydrochloric acid, and metallic platinum (Schützenberger, *Ann. Ch. Phys.* [2] xv. 100; *Zeitschr. f. Chem.* [2] iv. 321; *Jahresh.* 1868, p. 277).

PLATINUM-BASES, AMMONIACAL. The following observations on these compounds have been made by Hadow (*Chem. Soc. J.* [2] iv. 345). *Tetrammonio-platinoous chloride* (diplatossamine hydrochloride) is conveniently prepared by digesting platinoous chloride (obtained by heating platonic chloride) at a gentle heat with moderately strong ammonia, and evaporating the solution; the salt then crystallises in prisms containing $\text{N}^4\text{H}^{12}\text{PtCl}_2 + \text{H}^2\text{O}$. A hot solution of this salt yields with hot moderately concentrated nitric acid, a crystalline deposit of tetrammonio-platonic

nitrate-chloride (diplatinamine chlorhydronitrate; Gros' nitrate), $\text{N}^4\text{H}^{12}\text{Pt}^2(\text{NO}^3)_2\text{Cl}^2$, which by recrystallisation from water may be obtained in flat shining prisms. By boiling the solution of this salt for some hours with excess of silver nitrate (190 pts. to 460 pts. of Gros' nitrate) and a small quantity of nitric acid, it is converted into octammonio-diplatinic nitratoychloride, $\text{N}^8\text{H}^{24}\text{Pt}^2(\text{NO}^3)_2\text{OCl}^2$ (iv. 676):

From the solution of this last salt, sal-ammoniac throws down a crystalline precipitate having the composition $\text{N}^8\text{H}^{24}\text{Pt}^2\text{Cl}^2\text{O}$.

The di-ammonio- and tetrammonio-platinous compounds possess, like platinous chloride, the power of reducing permanganates. The tetrammonio-platinous salts are further characterised by their behaviour to platinous chloride, with which they form the green salt of Magnus (iv. 674). The latter may be regarded as the type of a class of salts in which the platinous chloride, PtCl^2 , is replaced by equivalent quantities of other chlorides, HgCl^2 , CdCl^2 , PdCl^2 , SnCl^2 , CuCl^2 . The tetrammonio-salts are further distinguished from the diammonio-salts by the characteristic blue or green colorations or precipitates produced in their solutions by nitrous acid (*vid. inf.*).

The ammonio-platinic salts do not reduce permanganates. Sal-ammoniac added to solutions of tetrammonio-platinic and octammonio-diplatinic salts not containing chlorine (salts of diplatinamine), throws down an insoluble hydrochloride; tetrammonio-platinic nitrate forms with sodium sulphate a crystalline precipitate made up of needles. Ammonio-platinic salts containing chlorine (chloroplatinamine salts) are not precipitated either by sal-ammoniac or by sodium sulphate; the nitrate is characterised by its behaviour with platinous chloride, which when added to its solution acidulated with nitric acid, throws down a coppered-coloured precipitate of variable composition; ammonio-platinic compounds not containing chlorine do not exhibit this reaction. The di- and tetrammonio-platinic salts are reduced by sulphurous acid to the corresponding ammonio-platinous salts. This copper-coloured salt is likewise produced when the green salt of Magnus is digested for some hours with an excess of a very dilute and strongly acid solution of octammonio-diplatinic nitratoychloride (Raewsky's nitrate). Its composition may be represented by the general formula $x\text{N}^4\text{H}^{12}\text{Pt}^2\text{Cl}^2\text{NO}^3$. By boiling with water it is resolved into the green salt of Magnus, tetrammonio-platinic nitrate-chloride (Gros' nitrate), and platinic chloride.

Hadlow has examined two of the compounds formed on passing nitrous acid into solutions of tetrammonio-platinous salts. A strongly acidulated solution of the nitrate thus treated yields a small-blue precipitate, composed of microscopic dodecahedrons; a similar solution of the hydrochloride yields a green precipitate, composed of microscopic feathery stars. The composition of the blue compound may be represented (empirically) by the formula $\text{N}^4\text{H}^{12}\text{Pt}^2(\text{NO}^3)_2\text{N}^2\text{O}^4$; that of the green compound by $2\text{N}^4\text{H}^{12}\text{Pt}^2\text{Cl}^2\text{N}^2\text{O}^3\cdot 2\text{HCl}$. Both these salts may be dried at 100° without decomposition, and dissolve in water with their original colour.

P. F. Cleve (*Acta Societatis Scientiarum Upsaliensis*, 1866; *Bull. Soc. Chim.* [2] vii. 12; *Jahresb.* 1867, p. 321) has examined a large number of salts belonging to the tetrammonio-platinous and tetrammonio-platinic series. From the fact that the platinic may be produced from the platinous compounds by direct oxidation, or direct addition of bromine, chlorine, &c., and the former from the latter by reduction, he infers that the compounds of these two series contain the same radicle, viz. $\text{N}^4\text{H}^{12}\text{Pt}^{2+}$, the oxide of the former series being $\text{N}^4\text{H}^{12}\text{PtO}_2$, that of the latter $\text{N}^4\text{H}^{12}\text{PtO}$.

Buckton (*Chem. Soc. Qu. J. v.* 213), by treating tetrammonio-platinous chloride with various metallic salts, obtained compounds of this chloride with the corresponding metallic chlorides; thus by mixing concentrated solution of tetrammonio-platinous chloride with acetate or nitrate of lead, a white crystalline precipitate is formed, which dissolves in hot water, and separates from the saturated solution in four-sided nacreous laminae, consisting of the double chloride, $\text{N}^4\text{H}^{12}\text{PtCl}^2\cdot\text{PbCl}^2$. It is insoluble in alcohol and in hydrochloric acid, and does not decompose at 170° . With solutions of mercuric chloride, zinc chloride, and cupric chloride, the compounds $\text{N}^4\text{H}^{12}\text{PtCl}^2\cdot\text{HgCl}^2$, $\text{N}^4\text{H}^{12}\text{PtCl}^2\cdot\text{ZnCl}^2$, and $\text{N}^4\text{H}^{12}\text{PtCl}^2\cdot\text{CuCl}^2$, are obtained, all of which crystallise in laminae. The copper-compound, which is yellow, is decomposed by boiling water into tetrammonio-platinic chloride, which separates, and cuprous chloride, which remains in solution; and on concentrating this solution and adding alcohol, a greenish precipitate is formed, consisting of the double chloride, $2\text{N}^4\text{H}^{12}\text{PtCl}^2\cdot\text{Cu}^2\text{Cl}^2$, which may also be formed by direct combination of the two constituent chlorides.

A class of salts isomeric with those just described has recently been discovered by Thomsen (*Oversigt over det Kongl. danske Videnskabernes Selskabs Forhandlinger*, 1867, p. 225; *Jahresb.* 1867, p. 278). They are formed when a solution of ammonio-platinous chloride, or of platinous chloride itself, is precipitated by the ammoniacal solution of a metallic salt. They are all crystallisable (mostly in long prisms), and usually coloured, the copper salt being violet, the nickel salt green, the cadmium salt orange-coloured, the zinc salt red, and the silver salt light rose-coloured. They all, excepting the silver salt, withstand a temperature of 120° , but decompose when more strongly heated, giving off sal-ammoniac, hydrochloric acid, and nitrogen, and leaving a residue of platinum and metallic chloride. In water and ammonia they are nearly or quite insoluble, but dissolve easily in hydrochloric acid, being thereby distinguished from the double chlorides obtained by Buckton, which dissolve easily in water, but with difficulty in hydrochloric acid. The cupric salt of this series was obtained some years ago by Millon a. Commaille (iv. 675), by adding platinic chloride to a concentrated ammoniacal solution of cuprous chloride. On neutralising its alcoholic solution with ammonia, the whole of the copper is precipitated as oxychloride, and the solution saturated with hydrochloric acid and left to evaporate, leaves ammonio-platinous chloride. If this copper salt suspended in water be treated with a quantity of hydrogen sulphide not sufficient to decompose it completely, the liquid becomes strongly alkaline from the presence of free ammonia, and if it be then filtered from the copper sulphide and neutralised with hydrochloric acid, it likewise yields crystallised ammonio-platinous chloride. From this reaction, and from its mode of formation, Thomsen assigns to the copper salt the formula $\text{PtCl} \cdot 2\text{NH}^4\text{Cl} \cdot \text{N}^2\text{H}^4\text{Cu}$. The relations of these isomerides are inferred from the following considerations. A solution of tetrammonio-platinous chloride, $\text{N}^4\text{H}^{12}\text{PtCl}^2$ or $2\text{NH}^4\text{Cl} \cdot \text{N}^2\text{H}^4\text{Pt}$, forms with an acid solution of cupric chloride, a precipitate of Buckton's copper salt, and with a solution of platinous chloride, a precipitate of the green salt of Magnus. Thomsen accordingly represents Buckton's salts as $\text{CuCl}^2 \cdot 2\text{NH}^4\text{Cl} \cdot \text{N}^2\text{H}^4\text{Pt}$, &c., and the salt of Magnus as $\text{PtCl}^2 \cdot 2\text{NH}^4\text{Cl} \cdot \text{N}^2\text{H}^4\text{Pt}$, the latter being intermediate between the salts of Buckton and of Thomsen, as shown by the following comparison:

Buckton's Salts.

$\text{R}^{\text{t}}\text{Cl}^2 \cdot 2\text{NH}^4\text{Cl} \cdot \text{N}^2\text{H}^4\text{Pt}$. Soluble in water; insoluble in hydrochloric acid.

Salt of Magnus.

$\text{Pt}^{\text{t}}\text{Cl}^2 \cdot 2\text{NH}^4\text{Cl} \cdot \text{N}^2\text{H}^4\text{Pt}$. Insoluble in water; insoluble in hydrochloric acid.

Thomsen's Salts.

$\text{Pt}^{\text{t}}\text{Cl}^2 \cdot 2\text{NH}^4\text{Cl} \cdot \text{N}^2\text{H}^4\text{R}$. Insoluble in water; soluble in hydrochloric acid.

The general formula of all these compounds is therefore $\text{R}^{\text{t}}\text{Cl}^2 \cdot 2\text{NH}^4\text{Cl} \cdot \text{N}^2\text{H}^4\text{Q}$, in which R or Q, or both of them, may consist of platinum.

A comprehensive theory of the constitution of the ammoniacal platinum-compounds has lately been proposed by Odling (*Chem. News*, xxi. 289): 1. The diammonio-platinous compounds are represented (as in Gerhardt's scheme, iv. 678) as containing the base *platosamine*, $\text{Pt}^{\text{t}}(\text{H}^2\text{N})^2$; and the diammonio-platinic compounds as containing the base *platinamine*, $\text{R}^2\text{Pt}^{\text{t}}(\text{H}^2\text{N})^2$, the symbol R denoting a monad chlorous radicle, Cl, HO, NO^2 , &c.

2. The tetrammonio-compounds, platinous and platinic, are supposed to contain the bases *amoplatosamine*, $\text{Pt}^{\text{t}}(\text{H}^2\text{N})^2$, and *amoplatinamine*, $\text{R}^2\text{Pt}^{\text{t}}(\text{H}^2\text{N})^2$, these bases containing the monad radicle ammonio-amidogen, H^2N^2 or $\text{H}^2\text{N} \cdot \text{H}^2\text{N}$, related to amidogen, H^2N , in the same way as the monad radicle ethyl, H^2C^2 or $\text{H}^2\text{C} \cdot \text{H}^2\text{C}$, is related to methyl, H^2C . The parallelism between these two series of nitrogen and carbon compounds may be illustrated by the following formulæ of methyl chloride, ethyl chloride, sal-ammoniac, and ammonio-chloride of silver:

The ammoniacal platinous and platinic compounds may therefore each be divided into the two groups of amic and ammonamic compounds. A fifth class is formed by the octammonio-platinic compounds, which contain the radicle *amo-di-platinamine*,

$R^ivPt^iv(H^2N)^4$. The following table exhibits the constitution of the principal ammoniacal platinum-compounds, formulated according to this scheme :

PLATINUM-BASES AND SALTS.

<i>Platosamine.</i>	<i>Amo-platosamine.</i>
$Pt^{iv}(H^2N)^2 \cdot 2HCl$	$Pt^{iv}(H^2N)^2 \cdot 2HCl + aq.$

<i>Amo-di-platinamine</i> (Racwsky's, &c.) . .	$\left\{ \begin{array}{l} Cl^2OPt^{iv}(H^2N)^2 \cdot 4HCl \\ Cl^2OPt^{iv}(H^2N)^2 \cdot 4HNO^2 + aq. \\ (NO^2)^2Pt^{iv}(H^2N)^2 \cdot 4HNO^2 + aq. \end{array} \right.$

Odling has also obtained the base or hydrate of the platosamine series, $Pt^{iv}(H^2N)^2 \cdot 2H(HO)$, by treating the hydrochloride with sulphuric acid, whereby it is converted into the sulphate, and decomposing this salt with baryta-water. It is extremely soluble in water, and readily crystallisable; yields a strongly alkaline solution; liberates ammonia from its salts; neutralises acids; absorbs carbonic acid from the air; and decomposes metallic salts, the resulting precipitates being however for the most part double compounds.

On the constitution of the platinum-bases, and of metallammonium compounds in general, see also Blomstrand (*Deut. chem. Ges. Ber.* iv. 40; *Chem. Soc. J.* [2] ix. 189).

PLATINUM-METALS, SEPARATION OF. Two methods for the separation of these metals have been given by Wolcott Gibbs: 1. By the action of *alkaline nitrites* on the compounds of the chlorides of these metals with potassium chloride (*Sill. Am. J.* [2] xxxiv. 341; *Chem. News*, vii. 61, 73, 97; *Jahresb.* 1863, p. 294).—2. By the action of *tuteo-cobaltic chloride* on these same double chlorides (*Sill. Am. J.* [2] xxxvii. 57; *Chem. News*, ix. 121; *Jahresb.* 1864, p. 287). The separation of rhodium from iridium, and of ruthenium from platinum, rhodium, and iridium, by the first of these methods is described in vol. v. pp. 103, 137.

On the separation of iridium and platinum from rhodium and ruthenium, see also Carey Lea (*Sill. Am. J.* [2] xxxviii. 81, 248; *Chem. News*, x. 279, 301; xi. 3, 13; *Jahresb.* 1864, p. 290).

Bunsen has described a new method of working up the platinum-residues obtained (in the Russian Mint)—after separating the platinum from the nitro-muriatic solution of the ore with potassium chloride—by treating the mother-liquor with metallic iron in order to precipitate the other metals. This precipitated residue contains all the platinum metals except osmium, and is particularly rich in rhodium, which may be advantageously prepared from it by the process described (*Ann. Ch. Pharm.* cxlvi. 265; *Bull. Soc. Chim.* [2] xi. 508; *Zeitschr. f. Chem.* [2] v. 3, *Jahresb.* 1868, p. 280; *Phil. Mag.* [4] xxvi. 253; *Chem. News*, xxi. 39).

POLYCHROÏTE. See SAFFRON.

PORPHYRINE. A base obtained by O. Hesse (*Ann. Ch. Pharm. Suppl.* iv. 40), together with chlorogenine, from a peculiar Australian bark. To prepare these bases, the strongly bitter concentrated aqueous extract of the bark is acidulated with sulphuric acid and mixed with mercuric chloride, which throws down the chlorogenine; and from the filtrate, freed from mercury by hydrogen sulphide, the porphyrine is obtained by neutralising with ammonia, precipitating the evaporated liquid with sodium carbonate, and agitating with ether; and purified by treating the ethereal solution with dilute sulphuric acid, again precipitating with sodium carbonate, extracting with ether, and decolorising with animal charcoal. On evaporating the ether, the porphyrine remains in the form of a varnish soluble in water and in alcohol, and partly crystallising from alcohol in thin white prisms. The solutions have an

alkaline reaction and a very bitter taste. Porphyrine melts at 82° , and resolidifies in the amorphous state. With strong nitric acid it exhibits a characteristic red colour. With sulphuric and hydrochloric acids it forms neutral salts, whose solutions, like those of quinine salts, exhibit a deep blue fluorescence when slightly acidulated. The sulphate is easily soluble in water and in alcohol, and crystallises in thin prisms; the hydriodide, mercurchloride, platinochloride, and aurochloride are yellow or white precipitates. In the solution of the acid sulphate, potassium dichromate produces a blood-red colour, which subsequently disappears, with formation of a yellow precipitate.

PORPHYROKINE. This base, which is a constituent of opium, dissolves in strong sulphuric acid containing nitric acid, to a black-brown liquid, becoming dark garnet-red at 150° (Dragondorff, *Jahresb.* 1864, p. 727).

PORPHYRY. The porphyritic rocks of the island of Hochland, in the Gulf of Finland, have been chemically examined by J. Lemberg (*Arch. für die Naturkunde Liv-, Ehst.- und Kurlands* [1] iv. 172, 337; *Jahresb.* 1867, p. 1015); the quartz-porphyrine of Monte Boeco in the Val San Pellegrino, by Tschermak (*Wien. Akad. Ber.* lv. [1] 287; *Jahresb.* 1867, p. 1022).

POTASSIUM. According to Baumhaner (*J. pr. Chem.* cii. 123), the oxidation of potassium on freshly-cut surfaces is attended with a faint luminosity visible in the dark.

Vogel (*Zeitschr. anal. Chem.* vii. 221) and Landolt (*ibid.* 20) have observed that potassium carbonate volatilises to a considerable extent at a strong red heat, and hence loss may arise in analytical processes, such as the valuation of tartar by ignition and titration of the residue, or in determining the quantity of ash yielded by plants, especially those which, like beet and sugar-cane, yield ashes consisting mainly of potassium carbonate.

For the preparation of pure caustic potash (or soda), Graeger (*J. pr. Chem.* xvi. 188) first heats the solution of the alkaline carbonate with silver carbonate to remove chlorine, and then renders it caustic by means of burnt marble. The filtration of the caustic solution may be conveniently effected through pounded marble, freed from the finest dust by washing with water.

Potassium Iodide.—On the preparation of this salt, see Fuchs (*Dingl. pol. J.* cxxx. 251; *Jahresb.* 1865, p. 162; also Mich. Pettenkofer, *Pogg. Ann.* cxxviii. 459; *Jahresb.* 1866, p. 152). On certain of its properties: Payen (*Compt. rend.* lxi. 466; *Jahresb.* 1865, p. 162).

SULPHIDES.—According to Schöne (*Pogg. Ann.* cxxxi. 380), the only definite sulphides of potassium that can be obtained in the dry way are the mono-, di-, tri-, and pentasulphide. The other polysulphides described by Berzelius appear to be merely mixtures, and the formation of one or the other sulphide depends in general, not so much on the use of particular reagents, or on the mode of preparation, as on the temperature. When potassium monosulphide or carbonate is fused with excess of sulphur in a porcelain crucible, and the heat continued at a uniform temperature till the weight becomes constant, the product formed at the lowest possible temperature (not above 600°) is the pentasulphide, at a dull red heat (up to 800°) the tetrasulphide, at a bright red heat (to 900°) the trisulphide. If the alkaline carbonate, instead of the sulphur, be used in excess, trisulphide is formed also at the lowest of the above temperatures. By passing vapour of carbon bisulphide over red-hot potassium sulphate, Schöne obtained, not the tetrasulphide which is said by Berzelius to be formed under these circumstances, but lower compounds, approximating in composition to K_2S^3 . When vapour of carbon bisulphide is passed over fused potassium carbonate, the sulphocarbonate is formed in the first instance, according to the equation:

and this at a higher temperature is resolved into a mixture of carbon and trisulphide: $2K_2CS^3 = C + 2K_2S^3$. In the wet way the following compounds were obtained:

The monosulphide crystallises from a solution of potash half saturated with hydrogen sulphide and evaporated in a vacuum, in deliquescent, four-sided prisms modified by truncations and sometimes tabular. The composition of these crystals, which are formed most readily at low temperatures, corresponds to the formula $K_2S \cdot 5H_2O$ or $K_2H_3SO \cdot 4H_2O$; they appear to be identical with the compound designated by Berzelius as crystallised sulphhydrate (*Gmelin's Handbook*, iii. 31). In a vacuum or when heated to 150° , they leave the hydrate $K_2S \cdot 2H_2O$; at a higher temperature they appear to give up all their water without loss of hydrogen sulphide.

Hydrated Potassium Sulphhydrate, $2KHS \cdot H_2O$, separates from a solution perfectly saturated with hydrogen sulphide, by evaporation in a vacuum, in well-defined,

colourless, transparent rhombohedrons, with shining surfaces. They are deliquescent, do not alter in a vacuum, or when heated to about 170° , but give off their water of crystallisation between 175° and 200° , retaining their form but losing their transparency. The anhydrous sulphhydrate melts at a dull red heat to a very mobile yellowish liquid, which gradually becomes darker, and solidifies on cooling to a flesh-coloured cake having a crystalline structure. The solutions of the sulphhydrate have an alkaline reaction, and give up half their sulphydric acid with tolerable facility when boiled. The solution of the monosulphide, even when it contains free alkali, is likewise slowly decomposed at the boiling heat, and appears ultimately to leave pure potassium hydrate, according to the equation: $K^2H^2SO + H^2O = H^2S + 2KHO$.

The polysulphides were obtained by boiling the solutions of the monosulphide or sulphhydrate with the calculated quantity of sulphur in vessels from which air was excluded.—The tetrasulphide crystallises by evaporation in a vacuum in thin orange-red laminae containing $K^2S^4 \cdot 2H^2O$, very hygroscopic, easily soluble in water, less soluble in alcohol. When heated, they first melt in their water of crystallisation, afterwards give it off, finally also hydrogen sulphide and sulphur, and leave a fused brown residue. The hydrate $K^2S^4 \cdot 8H^2O$ separates as a brownish oil on adding alcohol of 90 p. c. to a concentrated solution of the tetrasulphide or pentasulphide, in the latter case with separation of sulphur, which is taken up by the sulphide remaining in the alcoholic solution. The oil just mentioned yields, in contact with absolute alcohol, prismatic crystals apparently consisting of the preceding hydrate. The pentasulphide was not obtained in the solid state. Schöne finds that its solution is decomposed by prolonged boiling, with formation of hydrogen sulphide and potassium hyposulphite, probably according to the equation $K^2S^5 + 3H^2O = 3H^2S + K^2SO^4$, and that at the boiling heat it still takes up sulphur, which separates on cooling in microscopic octohedrons soluble in carbon bisulphide.

PROPANE. C^3H^8 . *Propyl Hydride*.—This hydrocarbon, the third member of the marsh-gas or paraffin series, is gaseous in the free state at ordinary temperatures, and occurs among the gases evolved from the petroleum springs of North America (Ronalds, *Chem. Soc. J.* [2] iii. 529. Lefevre, *Zeitschr. f. Chem.* [2] v. 185. Fouqué, *ibid.* 304). It is formed: 1. By the action of fuming hydriodic acid on several hydrocarbons or their derivatives (Berthelot, *Jahresh.* 1867, pp. 344, 346):

Phenol heated with hydriodic acid is reduced to benzene, which is then further converted into propane as above. Acetone yields propane, together with ethane and methane (Berthelot).

2. From secondary propyl iodide by the action of zinc and dilute hydrochloric acid:

Propane prepared by the last process may be purified by washing it successively with fuming sulphuric acid, with a mixture of sulphuric and nitric acid, and with soda-ley. If it be then collected over a strong solution of common salt, mixed with chlorine not in excess, and exposed to diffused daylight, an oily liquid is obtained containing a mixture of chlorinated derivatives of propane, which may be separated by fractional distillation. The lowest fraction, boiling at 42° – 46° , consists of normal propyl chloride, $CH^3-CH^2-CH^2Cl$. On heating this liquid to 200° for several hours with potassium acetate and glacial acetic acid, and decomposing the resulting acetic ether with potash-ley in sealed tubes at 120° , normal propyl alcohol, $CH^3-CH^2-CH^2OH$, is obtained, which when oxidised by chromic acid, yields nothing but propionic acid. The propyl alcohol may be isolated by treating the alcoholic distillate obtained by the action of potash on the acetate, with potassium

carbonate, whereupon a light oily liquid rises to the surface; and this, when dehydrated with potassium carbonate and anhydrous baryta boils between 80° and 90° , and may be separated by fractional distillation into a portion boiling between 80° and 85° , and another between 92° and 96° . The latter is the normal propyl alcohol; the former appears to be an acetal, $C^3H^{12}O^2$. The series of reactions above described affords a general method of converting a secondary alcohol into the normal primary alcohol.

The chief product of the action of chlorine on propane is ordinary propylene chloride, $C^3H^4Cl^2$, boiling between 94° and 98° . This chloride may be converted in the usual way into a glycol, yielding by oxidation carbonic and acetic acids, and therefore having the constitution of the already known propylene glycol, $CH^2-CHOH-CH^2OH$. It appears from these experiments that propane reacts with chlorine differently from ethane; for the latter is thereby converted into ethylene chloride, CH^2-CHCl^2 , in which both atoms of chlorine are attached to the same carbon-atom, whereas in propane the two hydrogen-atoms which are replaced by chlorine belong to different atoms of carbon (Schorlemmer, *Proc. Roy. Soc.* xvii, 372; *Ann. Ch. Pharm.* cl. 159).

The product of the action of chlorine on propane likewise contains more highly chlorinated compounds boiling between 100° and 200° . The latter are obtained in greater quantity by exposing the portion of liquid which boils above 80° to the further action of chlorine in direct sunshine for several days. The product is a liquid boiling between 120° and 200° , which by fractional distillation yields trichlorhydrin or trichloropropane, $C^3H^2Cl^3$, boiling between 150° and 160° . This liquid heated with dry potassium hydrate yields glycidic dichloride, $C^3H^4Cl^2$, which unites directly with bromine, forming the compound $C^3H^4Cl^2Br^2$. Hence it appears that propane and ethane differ also in the nature of their third chlorinated derivatives, propane yielding trichlorhydrin, the structure of which is most probably represented by the formula $CH^2Cl-CHCl-CH^2Cl$, whereas ethane yields the compound CH^3-CCl^3 . It is further to be observed that the substitution-products of primary propyl chloride are identical with those of the secondary chloride; for, as Linnemann has shown (*Ann. Ch. Pharm.* cxxxvi. 48; cxxxix. 17), when chlorine is passed into secondary propyl iodide (v. 891), secondary propylchloride is first formed, then probably propylene dichloride, and finally trichlorhydrin.

Tetrachloropropane, $C^3H^2Cl^4$, is obtained by exposing the liquid from which the trichlorhydrin has separated, to sunshine for several days, and then distilling. The product boils between 200° and 250° , and the portion distilling between 200° and 205° solidifies in the receiver to a crystalline mass of tetrachloropropane, which may be freed from an adhering oily chloride by pressure between paper, and obtained in stellate groups of small needles by recrystallisation from a hot-saturated alcoholic solution. It smells strongly like camphor, volatilises somewhat quickly when exposed to the air, melts when heated in a test-tube, and sublimes very rapidly; in a sealed capillary tube it melts at 177° to 178° , and resolidifies completely at 176° to 175° .

Hexachloropropane, $C^3H^2Cl^6$, is slowly produced by the action of chlorine in the brightest sunshine, and in presence of iodine, on the portion of the above-mentioned distillate which boils between 205° and 250° . It is a colourless liquid, smelling like camphor, and boiling without decomposition at 250° . It does not appear possible to replace more than six of the hydrogen-atoms of propane by chlorine (Schorlemmer, *Proc. Roy. Soc.* xviii. 29; *Ann. Ch. Phys.* clii. 159).

PROPARGYLIC ETHER. $C^3H^3O = \begin{smallmatrix} C^3H^3 \\ C^3H^3 \end{smallmatrix} O$ (Liebermann, *Ann. Ch. Pharm.*

cxxv. 266; *Jahresb.* 1865, p. 496).—Produced by the action of potassium ethylate on bromallylene; $C^3H^3Br + C^2H^5.HO = HBr + C^3H^3.C^2H^5.O$; more readily by the prolonged action of boiling alcoholic potash on tribromallyl, $C^3H^3Br^3$. The distillate, freed from a brominated oil by washing with water, yields with ammoniacal

silver-solution a white bulky precipitate of argentopropargylic ether, $\begin{smallmatrix} C^3H^2Ag \\ C^3H^3 \end{smallmatrix} O$ (iv.

728), which when treated with acids yields propargylic ether. This ether is a liquid having an offensive odour, boiling at 72° , forming a white precipitate with silver solution, yellow with ammoniacal cupric chloride. The silver-compound resembles that of allylene, but has a stronger odour and is amorphous; melts and detonates when heated, leaving a pyrophoric mass; and forms a silver-speculum when boiled with water. Mixed with a solution of iodine in potassium iodide, as long as decoloration ensues, and then distilled, it yields a transparent, colourless, fetid oil consisting of iodopropargylic ether, $\begin{smallmatrix} C^3H^2I \\ C^3H^3 \end{smallmatrix} O$. The silver-compound mixed with a large excess

of iodine in ethereal solution forms a viscid yellowish oil, $\begin{smallmatrix} C^3H^2I.I^2 \\ C^3H^3 \end{smallmatrix} O$, which gives off

iodine when heated. Iodopropargylic ether unites with bromine, forming the yellowish oily body $\begin{matrix} \text{C}^2\text{H}^1\cdot\text{Br}^2 \\ \text{C}^2\text{H}^3 \end{matrix} \text{O}$.

Propargylic ether may also be prepared by boiling trichlorhydrin with 3 pts. of potassium hydrate and a large quantity of alcohol. The alcoholic distillate yields with silver nitrate a dazzling white crystalline precipitate of the silver-compound $\text{C}^2\text{H}^1\text{Ag} \cdot \text{C}^2\text{H}^3 \cdot \text{O}$, from which propargylic ether is easily obtained by the action of nitric acid, less easily by treatment with excess of potash, a pungent silver-blackening substance being then likewise formed, probably acrolein (Bayer, *Ann. Ch. Pharm.* cxxxviii. 196).

By treating tribromallyl with a solution of potash in methyl alcohol, and the distillate with ammoniacal silver nitrate, the silver-derivative of methyl-propargylic ether, $\begin{matrix} \text{C}^2\text{H}^2\text{Ag} \\ \text{CH}^3 \end{matrix} \text{O}$, is obtained, as a lemon-yellow gelatinous precipitate, from which,

by the action of iodine dissolved in potassium iodide, the compound $\begin{matrix} \text{C}^2\text{H}^2\text{I} \\ \text{CH}^3 \end{matrix} \text{O}$ is obtained, as an oil which solidifies in needles at about 12° (Liebmann). See further, Liebermann a. Kretschmer (*Ann. Ch. Pharm.* clviii. 230; *Chem. Soc. J.* [2] ix. 527).

PROPIODIACETAMIDE, $\text{C}^2\text{H}^1\text{N}^2\text{O}^3 = \text{N}^2(\text{C}^2\text{H}^1\text{O})(\text{C}^2\text{H}^3\text{O})^2\text{H}^2$ or $\text{N}(\text{C}^2\text{H}^3\text{O})(\text{C}^2\text{H}^1\text{O})\text{H} \cdot \text{N}(\text{C}^2\text{H}^1\text{O})\text{H}^2$, is formed by heating propionitrile and acetic acid in molecular proportions to 200° for a few hours (Gautier, p. 525).

PROPIONE, $\text{C}^2\text{H}^3\text{O} = \text{CO}(\text{C}^2\text{H}^3)^2$.—This ketone is formed by the oxidation of diethoxalic acid with potassium dichromate and sulphuric acid:

It may be prepared by decomposing ethyl diethoxalate with potash, and, after distilling off the alcohol, treating the crude potassium diethoxalate with the oxidising mixture (Chapman a. Smith, *Chem. Soc. J.* [2] v. 173; *Jahresb.* 1867, p. 453). It is also produced, together with ethylcrotonic acid, by heating ethyl diethoxalate with fuming hydrochloric acid to 150° for several hours (Geuther, *Jahresb.* 1867, p. 455):

The propione obtained by either of these processes is identical in properties with that obtained by the methods of Morley, Freund, and Wanklyn (iv. 729).—Propione, doubtless also identical with this, is formed by heating 1 pt. of bromamylene with 3·4 pts. mercuric oxide, 4 pts. glacial acetic acid, and sufficient water to ensure the solution of the mercuric oxide when heated. On distilling off about one-fourth of the product, neutralising the distillate with potash, again distilling off the most volatile portion, and mixing this distillate with water, a ketone, $\text{C}^2\text{H}^3\text{O}$, is obtained, which boils between 90° and 100° , and does not unite with acid sulphites of alkali-metal (Linnemann, *Zeitschr. f. Chem.* [2] iv. 57).

Isomeric with propione, and capable of uniting with alkaline bisulphites, are methyl-propyl ketone, boiling at 101° ; methyl-isopropyl ketone, boiling at $98\cdot5^\circ$ (p. 768); ethyl-propyl aldehyde (b. p. 110°), from butyric acid (Limpricht a. von Usler, *Jahresb.* 1855, p. 509); methyl-butyl (b. p. 110°), from calcium butyrate (Friedel, *ibid.* 1858, p. 295); and valeraldehyde (b. p. 101°).

PROPIONIC ACID, $\text{C}^2\text{H}^3\text{O}^2 = \text{C}^2\text{H}^3\text{O} \cdot \text{OH} = \text{CH}^3\text{—CH}^2\text{—COOH}$.—This acid is formed: By reduction of iodopropionic acid with sodium-amalgam (Moldenhauer, *Jahresb.* 1864, p. 370); by heating methyl-crotonic acid with potash (Frankland a. Duppa, p. 829); and by heating argyrescin (from horse-chestnut bark) with potash (Rochleder, p. 59):

It is also found amongst the products of the dry distillation of wood (Anderson, *Chem. News*, xiv. 257. Barré, *Zeitschr. f. Chem.* [2] v. 445).

Acetyl-propionic Acid, $\text{C}^2\text{H}^3\text{O}^3 = \text{C}^2\text{H}^3(\text{C}^2\text{H}^3\text{O})\text{O}^2$.—The ethylic ether of an acid having this composition is produced by the action of ethyl chloracetate on the product of the action of sodium on ethyl acetate, and this ether boiled with caustic soda yields the corresponding sodium salt, $\text{C}^2\text{H}^3\text{O}^3\text{Na}$. The zinc salt, $(\text{C}^2\text{H}^3\text{O}^3)\text{Zn}$, and the calcium salt, $(\text{C}^2\text{H}^3\text{O}^3)\text{Ca}$, crystallise in colourless nacreous

laminæ; the silver salt, $C^2H^3O^2Ag$, is slightly soluble in water (Noeldecke, *Zeitschr. f. Chem.* [3] iv. 681).

Bromopropionic Acid. $C^2H^3BrO^2$ (see iv. 733).—*Dibromopropionic acid*, $C^2H^2Br^2O^2$, is formed by direct addition of 1 mol. bromine to acrylic acid, $C^2H^3O^2$, in aqueous solution; it may be crystallised by very slow evaporation, but becomes resinous by keeping, and gives off hydrobromic acid. The bromine is only partially removed from it by boiling with baryta-water, and not completely even by silver oxide till after prolonged action (Wichelhaus, *Jahresb.* 1867, p. 403).

Chloropropionic Acid. $C^2H^3ClO^2$ (Wichelhaus, *Ann. Ch. Pharm.* clxiii, 1; cxliv. 351; *Jahresb.* 1867, p. 399).—This acid exists in two modifications, the one (α) produced by the action of water on lactyl chloride, $C^2H^3OCl^2$, or chloropropionyl chloride, $C^2H^2ClO.Cl$, the other (β) by the action of phosphorus pentachloride on glyceric acid.

α *Chloropropionic acid* was first obtained by Ulrich (iv. 733), but not in the pure state. Buchanan (*Zeitschr. f. Chem.* [2] iv. 523) prepares it by distilling calcium lactate with 2 mol. PCl^3 , rectifying the product twice, collecting each time only the portion which boils above 111° , and mixing the resulting solution of lactyl chloride in phosphorus oxychloride with an equal quantity of water in a vessel cooled with water (not with ice). On subsequent distillation, the liquid separates into two layers, the upper of which distils over completely at 186° , and on subsequent rectification yields pure chloropropionic acid. Pure lactyl chloride free from phosphorus oxychloride is not completely decomposed by water, even after several hours' boiling.

β Chloropropionic acid is prepared by treating a salt of glyceric acid with 3 mol. phosphorus pentachloride; distilling off the greater part of the phosphorus oxychloride (chloropropionyl chloride remaining in the residue); then connecting the retort with an upright condenser; gradually pouring in absolute alcohol; filtering off the separated phosphate; leaving the alcoholic filtrate to itself for 24 hours; and then mixing it with common salt, which throws down ethyl chloropropionate. This ether is freed from phosphoric ether by washing with water, rectified after drying, and decomposed by baryta-water; and the acid separated from the aqueous solution of the resulting barium salt by sulphuric acid, is dissolved by agitation with ether (Wichelhaus).

The difference of constitution between the two isomeric acids may be represented by the following formulæ:

α Chloropropionic acid is a colourless transparent liquid, having a faint odour of acetic and butyric acids, and a sharp taste. It blisters the skin, mixes in all proportions with water, alcohol, and ether, boils at 186° , has a sp. gr. of 1.28 at 0° , and expands strongly by heat. It remains liquid at the temperature of a mixture of ice and salt (Buchanan). It forms a liquid chloride; its ethylic ether boils at 144° . It is easily decomposed by silver oxide, with formation of lactic acid; its barium salt is also decomposed when its solution is evaporated over the water-bath. Boiled with excess of silver oxide, it forms acetic and probably also formic acid (Wichelhaus).

β *Chloropropionic acid* forms fibrous tufts of crystals, smelling like creosote, melting and volatilising at 65° . Its chloride is crystalline. The ethylic ether boils at 150° – 160° . The barium salt separates from its solution by evaporation over the water-bath in shining scales and laminæ. The acid is but slowly decomposed by silver oxide; when heated with excess of the oxide, it throws down metallic silver and forms carbacetoxylic acid, $C^2H^3O^4$, isomeric with malonic acid, but monobasic:

The boiling point of α chloropropionic acid is the same as that of chloracetic acid: hence it cannot be homologous with the latter; the true homologue of chloracetic acid, $CH^2Cl-COOH$, is β chloropropionic acid, CH^2Cl-CH^2-COOH .

Iodopropionic Acid. $C^2H^3IO^2$.—There are two modifications of this acid, corresponding with those of chloropropionic acid, viz. the α acid obtained from lactic, and the β acid from glyceric acid.

α *Iodopropionic acid* is prepared by digesting syrupy lactic acid with 1 mol.

phosphorus di-iodide, pouring the mixture at the termination of the reaction into water, agitating with ether, and evaporating the ethereal solution. The acid then remains in the form of an oil nearly insoluble in water, whereas β iodopropionic acid, obtained by the action of hydriodic acid or of phosphorus iodide on glyceric acid (iv. 733), crystallises easily and well (Wichelhaus, *loc. cit.*).

β Iodopropionic acid boiled with silver oxide not in excess, yields a silver salt, convertible by double decomposition into a zinc salt, having the composition $(C^3H^3O^2)^2Zn$, and the properties of ordinary zinc lactate; but the mother-liquor after a while deposits crystals easily soluble in water and in alcohol, and having nearly the composition of the zinc salt of paralactic or sarcolactic acid. Wichelhaus regards the latter as the primary product of the transformation of β iodopropionic acid, and supposes that it is afterwards converted into ordinary lactic acid by prolonged boiling with the silver oxide; he thence infers that α chloro- and α iodo-propionic acid are analogous in constitution to ordinary lactic acid; β chloro- and iodopropionic acid to paralactic acid:

Wislicenus (*Zeitschr. f. Chem.* [2] iv. 683) also finds that β iodopropionic acid boiled with recently precipitated silver oxide, yields lactic acid, and is of opinion that the acid $C^3H^3O^2$, called *hydracrylic acid*, which Beilstein obtained from β iodopropionic acid by the same process, was in all probability nothing but lactic acid.

Scofield, on the other hand (*ibid.* v. 423), has obtained by similar means an acid, $C^3H^3O^2$, some of the salts of which differ in character from those of either of the known lactic acids, and from those of the isomeric methyl-glycollic acid. This acid he designates as *glyceralddehydic acid*, regarding it as the aldehyde of glyceric acid. Beilstein's hydracrylic acid he regards as an anhydride of this acid. (See LACTIC ACID, p. 770.)

β Iodopropionic acid heated with excess of metallic silver is converted into adipic acid, $C^6H^{10}O^4$ (Wislicenus, *ibid.* 680):

Phenyl-propionic Acid. $C^9H^{10}O^2 = C^8H^9(C^3H^3O^2)$.—Syn. with HYDROCINNAMIC ACID. See CINNAMIC ACID (p. 468). Under the same head are also described the chlorine, bromine, and iodine derivatives of phenyl-propionic acid, also of oxyphenyl-propionic or phenyl lactic acid, $C^9H^{10}O^3$.

Nitrophenyl-propionic acid, $C^9H^8(NO^2)O^2 = C^8H^7\{NO^2\}_{C^3H^3O^2}$, is formed by treating hydrocinnamic acid with fuming nitric acid in a cooled vessel; when purified by separation from its sodium salt and recrystallisation from hot water, it forms feathery groups of faintly yellow crystals, very slightly soluble in cold, more easily in warm water, moderately soluble in alcohol and ether. It softens when heated, melts completely at 163° , and solidifies to a radio-crystalline mass on cooling. Its salts are for the most part easily soluble and difficult to crystallise; the lead and silver salts are yellowish precipitates. The acid oxidised with chromic acid mixture is converted into paranitrobenzoic acid: hence it belongs to the para series.

Amidophenylpropionic acid, $C^9H^8(NH^2)O^2 = C^8H^7\{NH^2\}_{C^3H^3O^2}$, is formed, together with hydrocarbostyrol (p. 715), by treating the nitro-acid with tin and hydrochloric acid, and remains in the mother-liquor after the hydrocarbostyrol has been separated. It crystallises in groups of quadratic prisms, melting at 131° and decomposing at higher temperatures. It unites both with bases and with acids; but the salts which it forms with bases are unstable and difficult to crystallise. Its combinations with acids, on the other hand, crystallise well: the *hydrochloride*, $C^9H^{11}NO^2.HCl$, in groups of four-sided prisms; the *sulphate*, $2C^9H^{11}NO^2.H^2SO^4$, from water, in large nodular groups; from alcohol it is precipitated by ether in silky needles; the *nitrate* separates from solution in warm dilute nitric acid in fine crystals.

Chloride of Diazophenylpropionic acid, $C^9H^7N^2O^2Cl = C^8H^6\{N=NCl\}_{C^3H^3O^2}$, is produced by passing nitrous acid vapour to saturation into a solution of dry hydrochloride of amidophenylpropionic acid in absolute alcohol, and crystallises in four-sided needles which detonate when heated. Their aqueous solution when warmed gives off large
Sup.

quantities of nitrogen, and the remaining liquid contains paraoxyphenylpropionic acid, $C^6H^4 \begin{Bmatrix} OH \\ C^3H^2O \end{Bmatrix}$, identical with hydroparacoumaric acid (p. 716):

Parabromophenyl-propionic acid, $C^6H^4BrO^2$, produced by the action of bromine on hydrocinnamic acid (p. 468), is converted by oxidation into parabromobenzoic acid.

Phenyl-propionic Acid. $C^6H^5O^2$ (Glaser, *Zeitschr. f. Chem.* [2] iv. 328).—This acid, related to phenyl-propionic acid in the same manner as stearic to stearic acid, is produced by the action of sodium and carbon dioxide on monobromocinnamene; also by abstraction of HBr from α -bromocinnamic acid, $C^6H^7BrO^2$, by means of alcoholic potash. (β -bromocinnamic acid treated in this manner yields an oily acid, p. 468.) It crystallises from water or from carbon bisulphide in long white silky needles melting at 136° – 137° , and subliming at the same temperature in slender needles. Under water it melts at 80° to a colourless oil, which dissolves on further heating. The acid dissolves easily in ether, and still more in alcohol. The *barium salt*, $(C^6H^5O^2)^2Ba$, crystallises by slow evaporation in square tables containing 1 mol. H^2O ; by evaporation over sulphuric acid in needles containing $2H^2O$; and from a solution cooled to a low temperature, in tufts of needles containing $3H^2O$. By boiling either of these hydrates with absolute alcohol, the anhydrous salt is obtained as a pulp of needle-shaped crystals. The anhydrous salt begins to decompose at 115° , and at higher temperatures gives off a yellowish oil (acetenyl-benzene?). The *potassium salt*, $C^6H^5O^2K$, is a crystalline powder very soluble in water. The *silver salt*, $C^6H^5O^2Ag$, is a very sparingly soluble precipitate; the *lead salt*, a white amorphous precipitate; the *copper salt*, a blue precipitate consisting of small laminae; with *ferric chloride* a yellow precipitate is obtained.

The relations between phenyl-propionic, cinnamic, and phenyl-propionic acids are exhibited by the following formulæ:

being similar to those between ethane, ethylene, and ethine or acetylene:

PROPIONIC ALDEHYDE. $C^3H^4O = C^2H^3.CO.H$.—Rossi (*Compt. rend.* lxx. 129) has obtained this compound by the dry distillation of a mixture of the calcium salts of formic and propionic acids (the latter prepared from ethyl cyanide). The distillate, after drying with calcium chloride, yielded by fractional distillation, $\frac{2}{3}$ of its weight of pure propionic aldehyde,* a small quantity of butyric aldehyde, and a liquid boiling at 80° – 100° , which apparently was not an aldehyde. Propionic aldehyde is a clear mobile liquid, having a pungent odour, boiling at 49.5° under a pressure of 740 mm., and having a sp. gr. of 0.8047 at 0° . According to Pierre a. Puchot, propionic aldehyde prepared by oxidation of normal propyl alcohol boils at 46° , and has a sp. gr. of 0.8329 at 0° , 0.8201 at 9.7° , and 0.7906 at 32.6° . Propionic aldehyde dissolves in water, but not in all proportions. It oxidises readily in the air, reduces ammoniacal silver solution, dissolves in acid sodium sulphite, but without separation of crystals, and is decomposed by heating with potash. By the action of water and sodium-amalgam it is reduced to normal propyl alcohol (Rossi).

PROPIONITRILE. See ETHYL CYANIDE, under CYANIDES (p. 524).

PROPIONYL BROMIDE. $C^3H^5O.Br$.—Produced by gradually adding 2 mol. PBr^2 to 3 mol. propionic acid in a cooled retort, and subsequently distilling. When

* The statement of Siersch (*Ann. Ch. Pharm.* cxlii. 115) that propionic aldehyde is not formed by this reaction, and consequently that the method cannot be employed for the synthetic production of the primary alcohols, is therefore disproved.

purified by repeated rectification, it is a fuming liquid having a peculiar odour resembling that of acetic acid, and also that of salted meat. Sp. gr. 1.465 at 14°. Boiling point 96°-98°. With water it becomes hot and is converted into propionic and hydrobromic acid (Sestini, *Bull. Soc. Chim.* [2] xi. 468).

PROPIONYL IODIDE. C^3H^5OI .—Obtained by adding 19.6 pts. iodine by small portions to a mixture of 11.1 pts. propionic acid and 1.6 pt. dry phosphorus, cooling and agitating, then distilling, rectifying over phosphorus, and finally decolorising the distillate by agitation with mercury. It boils between 127° and 128°, sinks in water, and is immediately decomposed thereby (Sestini, *loc. cit.*).

PROPYL ALCOHOLS and ETHERS. 1. *Normal Propyl Alcohol*, $CH^3-CH^2-CH^2OH$, was first obtained, though not quite pure, by Chancel in 1853, from the fusel-oil of the residues left in the distillation of brandy from wine: he found it to boil at 96° to 97° (about 19° higher than ethyl-alcohol). Chancel has lately subjected propyl alcohol obtained from the same source to further examination (*Compt. rend.* lxxviii. 659, 726); he now finds that it boils at 97°-100°, but that a very small quantity of water lowers the boiling point considerably. Sp. gr. 0.813 at 13° (water at 4° = 1). It forms a hydrate, $C^3H^7O.H^2O$, boiling constantly at 87.5° (under a pressure of 738 mm.), but decomposed by potassium carbonate. The alcohol is insoluble in cold concentrated solution of calcium chloride, and turns the plane of polarisation to the left; $[\alpha] = -5^\circ$. By oxidation with chromic acid, it is almost wholly converted into propionic acid; if the quantity of the oxidising agent is comparatively small, propionic aldehyde, C^3H^5O , is likewise formed. Pierre n. Puchot (*Compt. lxxvi.* 302) by distilling fermented beet-molasses, obtained, towards the end of the distillation, a mixture of amyl, butyl, and propyl alcohols. The propyl alcohol separated therefrom by fractional distillation boils at 98.5°, and is therefore also normal propyl alcohol. It has a sp. gr. of 0.820° at 0°, 0.812 at 10.3°, 0.780 at 51.1°, and 0.749 at 84°. The propyl iodide obtained from it boils at 104.5°, the acetate at 105°. Fittig, König, a. Schäffer (*Zeitschr. f. Chem.* [2] iv. 44) have demonstrated the existence of the same alcohol in a commercial fermentation-product designated as propylic alcohol and containing also amylic and ethylic alcohols. This liquid treated with bromine and phosphorus yielded a mixture of bromides from which, by fractionation, propyl bromide was obtained boiling at 71° to 71.5°. This therefore is normal propyl bromide, for its boiling point differs from that of ethyl bromide by the same amount (29°) as that of ethyl bromide (42°) differs from that of methyl bromide (13°). Hence the alcohol in question is normal propyl alcohol. Chapman a. Smith (*Chem. Soc. J.* [2] vii. 198) also, by subjecting the mixture of alcoholic bromides prepared from a fusel-oil of unknown origin to fractional distillation, obtained a propyl bromide boiling at 70.3° to 70.8°, and having a sp. gr. of 1.3532 at 26°. This bromide was converted into the corresponding acetate by treatment with potassium acetate and glacial acetic acid, and the acetate into the alcohol by heating it in a sealed tube with strong aqueous ammonia: the contents of the tube were neutralised with acetic acid and distilled, and the alcohol separated from the distillate by potassium carbonate. This alcohol boiled at 97°-98°, had a sp. gr. of 0.8120 at 16°, and yielded propionic acid by oxidation. The iodide, C^3H^5I , obtained from it by treatment with hydriodic acid boiled at 102°-103°, and had a sp. gr. of 1.7343 at 16°.

Schorlemmer, as already observed (p. 957), has obtained normal propyl alcohol from propane prepared by the action of zinc and hydrochloric acid on isopropyl iodide; this affords the means of converting isopropyl compounds into normal propyl compounds; the alcohol thus obtained (not quite pure) boiled at about 96°.

Linnemann (*Ann. Ch. Pharm.* cxlviii. 251) has prepared normal propyl alcohol from ethyl alcohol in the same manner as he formerly obtained ethyl alcohol from methyl alcohol, namely by converting it first into ethyl cyanide or propionitrile, then successively into propionic acid, propionyl chloride, and propionic anhydride (by heating the chloride with sodium propionate), and treating the anhydride with sodium-amalgam in the same manner as in the preparation of ethyl alcohol from acetic anhydride (p. 592). The propyl alcohol thus obtained boiled between 84° and 91°, and was therefore not quite pure. By oxidation with chromic acid it yielded propionic acid.

Lastly, Rossi (*Compt. rend.* lxx. 129; *Zeitschr. f. Chem.* [2] vi. 141) has obtained normal propyl alcohol by the action of nascent hydrogen on propionic aldehyde prepared from ethyl alcohol as already described (p. 962). The aldehyde was dissolved in 15-20 times its weight of water, sodium-amalgam was introduced into the liquid by small portions, and an equivalent quantity of sulphuric acid added at the same time. As soon as the liquid ceased to reduce silver-solution, it was distilled; the distillate was filtered to separate a few drops of an insoluble oily substance; and the propyl alcohol was separated from its aqueous solution by distillation and addition

of potassium carbonate. The product amounted to $\frac{2}{3}$ of the theoretical quantity. Propyl alcohol thus obtained boils at 96° (bar. at 743 mm.), and has a sp. gr. of 0.8205 at 0° . By oxidation with chromic acid it yields pure propionic acid.

The following table exhibits the boiling points and specific gravities of the normal propyl alcohol and the corresponding ethers :

Normal Propylic Alcohol and Ethers.

	Boiling Point	Specific Gravity	Observer
Alcohol, C^3H^7OH	96° – 97°	0.813 at 13°	Chancel.

Isopropyl Alcohol. $CH^3-CHOH-CH^3$.—The formation of this alcohol from acetone, propylene, or glycerin has been already noticed (v. 889). It is also formed: a. By the action of nascent hydrogen on acrolein, C^3H^4O , and on propylene oxide, C^3H^4O (Linneman, *Ann. Ch. Pharm.* cxxxiii. 132 cxi. 178).— β . From ethyl alcohol,

by converting the latter, first into ethyl cyanide or propionitrile, $\text{CH}_3\text{—CH}_2\text{—CN}$, then into propylamine, $\text{CH}_3\text{—CH}_2\text{—CH}_2\text{—NH}_2$, by the action of nascent hydrogen, and the latter into propyl alcohol by heating the aqueous solution of its nitrite (p. 63). This series of actions might rather be expected to yield normal propyl alcohol, $\text{CH}_3\text{—CH}_2\text{—CH}_2\text{OH}$; but the greater part of the alcoholic liquid obtained was found to boil at $83^\circ\text{--}85^\circ$, and to yield acetone by oxidation: it was therefore isopropyl alcohol. A smaller portion boiled at $93^\circ\text{--}96^\circ$, and appeared to be the same alcohol mixed with a small quantity of a foreign substance. The change of the propyl radicle from normal propyl, $\text{CH}_2\text{CH}_2\text{CH}_3$, into isopropyl, $\text{CH}(\text{CH}_3)_2$, probably takes place in the conversion of the propionitrile into propylamine. The formation of the alcohol is accompanied by that of a nitrogenous substance, $\text{C}^3\text{H}^4\text{N}^2\text{O}$, boiling between 200° and 205° , having a sp. gr. of 0.924 at 14° , and slightly soluble in water (Siersch, *Ann. Ch. Pharm.* cxliv. 137; see also Linnemann, *ibid.* cl. 370).— γ . Dichlorhydrin, $\text{CH}_2\text{Cl—CH(OH—CH}_2\text{Cl}$, dissolved in ether free from alcohol, but not anhydrous, is converted by sodium-amalgam into isopropyl alcohol, mixed with products of higher boiling point (Buff, *Zeitschr. f. Chem.* [2] iv. 124).— δ . Glycolic iodhydrin, $\text{C}^3\text{H}^4\text{I}(\text{OH})$, treated with zinc-methyl, yields the compound $\left\{ \begin{smallmatrix} \text{C}^3\text{H}^4 \\ \text{CH}^3\text{Zn} \end{smallmatrix} \right\} \text{O}$, and this, when heated with water under pressure, is converted into isopropyl alcohol (Butlerow u. Ossokin, p. 64). Yssel de Schepper u. Tak (*ibid.* iv. 520) have obtained isopropyl alcohol from the portion of grain fusel-oil boiling at $93^\circ\text{--}98^\circ$, by boiling it with potash in a flask with upright condenser and distillate. The distillate dehydrated with sodium carbonate yielded a propyl alcohol boiling at $83^\circ\text{--}84^\circ$, and convertible into an iodide boiling at $72^\circ\text{--}91^\circ$.

Isopropyl alcohol subjected to a series of processes exactly similar to that by which it is formed from ethyl alcohol, yields an alcohol, $\text{C}^4\text{H}^6\text{O}$, probably consisting of isobutyl alcohol (Siersch, *Ann. Ch. Pharm.* cxlviii. 261; *Jahresb.* 1868, p. 436).

The *haloid isopropyl ethers*, formed by treating the alcohol with the corresponding hydracids, exhibit the following properties:

	Boiling point.	Sp. gr.
Isopropyl chloride . . .	36° to 38° at 741 mm.	0.874 at 10°
„ bromide . . .	60 „ 63° „ 739 „	1.320 „ 13°
„ iodide . . .	89 „ 90° „ 735 „	1.70 „ 15°

The action of bromine on isopropyl alcohol gives rise (inasmuch as acetone and hydrobromic acid are formed by abstraction of water) to isopropyl bromide, propylene bromide, and substitution-products of acetone, from which, by the action of potash, bromoform may be produced. Isopropyl chloride is but little attacked by chlorine or bromine. Isopropyl iodide is converted, by the action of chlorine or of hydrochloric acid and potassium chlorate, into a product boiling between 90° and 170° , from which, by fractional distillation, trichlorhydrin, $\text{C}^3\text{H}^4\text{Cl}_3$ (b. p. $154^\circ\text{--}160^\circ$; sp. gr. 1.417 at 15°), may be separated. Bromine converts isopropyl iodide into the bromide. When equal volumes of bromine and isopropyl bromide are heated with water to $140^\circ\text{--}150^\circ$, monobromisopropyl bromide, $\text{C}^3\text{H}^4\text{Br}_2$, is formed, together with further substitution-products. This compound is identical with propylene bromide, boils at $110^\circ\text{--}143^\circ$, and has a sp. gr. of 1.954 at 150° . By silver acetate in presence of glacial acetic acid it is converted into propylene diacetate (b. p. $180^\circ\text{--}185^\circ$), and by alcoholic potash into monobromopropylene, $\text{C}^3\text{H}^4\text{Br}$ (b. p. $56^\circ\text{--}58^\circ$; sp. gr. 1.40 at 13°). This last compound unites with bromine, forming the compound $\text{C}^3\text{H}^4\text{Br}_2$ (b. p. $194^\circ\text{--}196^\circ$; sp. gr. 2.390 at 10°), identical with that previously obtained by Wurtz (*Jahresb.* 1857, p. 462) and by Cahours (*ibid.* 1850, p. 496). Heated with silver acetate and glacial acetic acid to $110^\circ\text{--}120^\circ$, it is converted, as shown by the equation,

into *dibromopropylene*, $\text{C}^3\text{H}^4\text{Br}_2$ (b. p. $127^\circ\text{--}131^\circ$; sp. gr. 1.98 at 15°), which is identical with allylene bromide, inasmuch as, when treated with sodium, it gives off a gas exhibiting all the properties of allylene.

When isopropyl bromide and water are heated with 2 mol. bromine to $110^\circ\text{--}120^\circ$, a colourless liquid is formed, which on distillation at 180° yields isopropyl bromide and propylene bromide, whilst the residue contains a mixture of more highly brominated substitution-products. After prolonged standing in the cold, it deposits a large quantity of crystallised *tribromisopropyl bromide*, $\text{C}^3\text{H}^4\text{Br}_3$. Br, while the expressed oily mother-liquor contains, in the portions boiling between 180° and 200° , *dibromisopropyl bromide*, $\text{C}^3\text{H}^4\text{Br}_2$. Br. This compound is converted by silver oxide into an easily soluble silver salt, an oily liquid insoluble in water, boiling above 160° ,

and glycerin. Tribromoisopropyl bromide dissolves easily in ether, chloroform, and benzol, sparingly in cold, more easily in boiling alcohol, from which it crystallises in white needles. It melts at 69° , and is decomposed by distillation. It is very easily decomposed by silver oxide or acetate. It is isomeric with dibromopropylene bromide, the bromine-compound of glycidic dihydrobromide, and allylone tetrabromide (Linne-mann, *Ann. Ch. Pharm.* cxxxvi. 37; *Jahresb.* 1865, p. 488). On the action of bromine on isopropyl alcohol, see also Friedel (*Comp. rend.* lx. 346; *Jahresb.* 1865, p. 491).

Isopropyl iodide treated with zinc and hydrochloric acid is converted into propane, C^3H^8 (Schorlemmer, p. 957).

The following isopropyl ethers have been obtained by the action of isopropyl iodide on the corresponding silver salts: *Isopropyl Nitrite*, $C^3H^7NO^2$, purified by quickly washing it with milk of lime and drying over fused and pulverised calcium nitrate (it decomposes calcium chloride), is a faintly yellow inflammable liquid smelling of nitrous acid. Boiling point 45° at 762 mm. Sp. gr. 0.856 at 0° , 0.844 at 25° . The *nitrate*, $C^3H^7NO^3$, washed with alkaline carbonate and dried over calcium chloride, forms a colourless, mobile, inflammable liquid, burning with a white feebly luminous flame, and smelling like nitric ethers in general. Its overheated vapour explodes with violence. Boils under ordinary pressure at 100° – 102° . Sp. gr. = 1.054 at 0° ; 1.036 at 19° . Optically inactive. Heated to 100° – 110° for several days with excess of ammonia, it yields a mixture of mono- and di-isopropylamine. *Isopropyl Butyrate*, $C^3H^7O^2.CH(CH^3)^2$, is a colourless, mobile liquid, having an odour somewhat like that of butyric acid, burning with a bright flame, boiling at 128° under pressure of 755 mm. Sp. gr. = 0.8787 at 0° ; 0.8652 at 13° . Optically inactive. The *valerate*, $C^3H^7O^2.CH(CH^3)^2$, resembles the butyrate, boils at 142° under pressure of 756 mm., has a sp. gr. of 0.8702 at 0° , 0.8538 at 17° . The *benzoate*, $C^3H^7O^2.CH(CH^3)^2$, is a fragrant, somewhat viscid liquid, difficult to set on fire, but burns with a bright flame giving off irritating vapours. Boiling point 218° at 762 mm. Sp. gr. = 1.054 at 0° ; 1.013 at 25° . The *succinate*, $C^3H^7O^4.(C^3H^7)^2$, is a viscid liquid having a rather agreeable odour; burns with a bright flame, giving off vapours which irritate the eyes. Boiling point 228° at 761 mm. Sp. gr. = 1.009 at 0° ; 0.997 at 18.5° (Silva, *Compt. rend.* lxxviii. 1476; lxi. 416; *Zeitschr. f. Chem.* [2] v. 508, 638).

Isopropyl sulphide, $(C^3H^7)^2S$, produced by heating the iodide with potassium mono-sulphide to 100° in alcoholic solution, is a colourless liquid, of offensive odour, boiling at 105° , and yielding with mercuric chloride in alcoholic solution a crystalline precipitate of the compound $(C^3H^7)^2S.HgCl^2$. The *sulphhydrate*, or *isopropyl mercaptan*, $(C^3H^7)HS$, prepared in like manner with potassium sulphhydrate, is a colourless foid liquid boiling at about 45° , and forming with mercuric oxide a white powder consisting of the compound $(C^3H^7)^2HgS^2$, which crystallises from boiling alcohol in white laminae. The *sulphocyanate*, $C^3H^7N.CNS$, prepared in like manner with potassium sulphocyanate, is a colourless liquid boiling at 149° – 151° , and having a sp. gr. of 0.963 at 20° . It does not unite with ammonia (L. Henry, *Deut. chem. Ges. Ber.* 1869, 495).

PROPYLAMINES. *Normal Propylamine*, $N \begin{Bmatrix} CH^2CH^2CH^3 \\ H^2 \end{Bmatrix}$, originally obtained

by Mendius by hydrogenation of propionitrile (v. 891), is also produced by the action of boiling potash on the mixture of propyl cyanate and cyanurate obtained by distilling normal propyl iodide with silver cyanate. When purified by conversion into hydrochloride, and separation therefrom by anhydrous baryta, it is a strongly alkaline liquid, boiling at 40° – 50° , and having a sp. gr. of 0.7283 at 0° , 0.7134 at 21° . It forms with solutions of aluminium salts a precipitate which is soluble in excess. The platinochloride, $2(C^3H^7N.HCl).PtCl^4$, crystallises in orange-yellow clinorhombic prisms (Silva, *Zeitschr. f. Chem.* [2] v. 638).

Isopropylamine, $N \begin{Bmatrix} CH(CH^3)CH^3 \\ H^2 \end{Bmatrix}$, is produced as a formate by the action of hydrochloric acid on isopropyl carbamine. (See CYANIDES, p. 530.) On distilling the product, formic acid passes over and hydrochloride of isopropylamine remains behind. The base liberated therefrom by strong potash-ley, distilled over fragments of fused potash into a well-cooled receiver, and dehydrated with anhydrous baryta, is a very mobile, strongly ammoniacal, sweetish liquid, having a not unpleasant odour, easily soluble in water, boiling at 31.5° – 32.5° . The *hydrochloride* is very deliquescent, soluble in absolute alcohol, crystallises when evaporated in a vacuum in cubes (the normal hydrochloride forms square plates, v. 891), melts at 139.5° , undergoes partial dissociation in a vacuum at 150° , and is partly converted by prolonged heating to 100° into a non-crystallisable rose-coloured liquid. The *platinochloride* crystallises in golden-

yellow laminæ or flattened needles, moderately soluble in water, somewhat soluble in a mixture of equal volumes of alcohol and ether (Gautier, *Compt. rend.* lxvii. 723).

Isopropylamine is also produced, together with di-isopropylamine, by distilling crude isopropyl cyanide (from isopropyl iodide and potassium cyanide) with hydrochloric acid. The two bases liberated from the resulting mixture of hydrochlorides (which is free from sal-ammoniac) are easily separated by distillation. Isopropylamine thus obtained boils at 31.5° under a pressure of 743 mm., and has a sp. gr. of 0.690 at 18°, converted by nitrous acid into isopropyl alcohol (Siersch, *Zeitschr. f. Chem.* [2] v. 145).

Di-isopropylamine, $\text{NH}(\text{C}^3\text{H}^7)_2$, is a transparent, easily inflammable liquid, slightly soluble in water, having a faint ammoniacal odour, and a soapy taste. Boils at 83.5° to 84° under a pressure of 743 mm. Sp. gr. 0.722 to 22°. The *hydrochloride* forms very deliquescent needles; the *platinochloride* large reddish-yellow tables, easily soluble in water and in alcohol, sparingly in ether-alcohol (Siersch).

PROPYLENE. C^3H^6 .—This hydrocarbon is found among the products obtained by the action of 1 mol. zinc ethyl on 2 mol. allyl iodide (Wurtz, *Bull. Soc. Chim.* [1863] v. 51); it is also formed, together with ethyl bromide, by the action of zinc-ethyl on bromoform (Alexeyeff a. Beilstein, *ibid.* [2] ii. 51):

According to Butlerow (*Ann. Ch. Pharm.* cxlv. 271), the propylene obtained from allyl iodide and hydriodic acid is identical with that formed by decomposition of amyl-alcohol, and has probably the constitution represented by the formula $\text{CH}^3\text{—CH=CH}^2$. Propylene from either of these sources is absorbed by hydriodic acid, forming isopropyl iodide, $\text{CH}^3\text{—CHI—CH}^2$, and exhibits one and the same reaction with hypochlorous acid. The same propylene is obtained by heating methyl-chloraceto, $\text{CH}^3\text{—Cl}^2\text{—CH}^2$, with sodium to 130°–150°; the gas thereby evolved forms with bromine a compound, $\text{C}^3\text{H}^6\text{Br}^2$, boiling at 141°–143°, and exhibiting all the properties of ordinary propylene bromide. But by treating acetone with phosphorus chlorobromide, PCl^3Br^2 , a compound, $\text{C}^3\text{H}^6\text{Br}^2$, is obtained, boiling at 113° to 116°, and having a sp. gr. of 1.8149 at 0°. This bromide gradually dissolves in water at 160°, forming a liquid which smells like acetone, and when heated to 100° with silver benzoate, yields, together with benzoic acid, a body crystallising in the same form as that obtained by Oppenheim (*infra*) from the hydriodide of chloropropylene.

By potassium permanganate propylene is oxidised to acetic and formic acids (Truchot, *Compt. rend.* lxiii. 274); by a solution of crystallised chromic acid in a small quantity of water, it is converted into acetone, $\text{C}^3\text{H}^6\text{O}$ (Berthelot, *Ann. Ch. Pharm.* cl. 373).

Propylene Chloride, $\text{C}^3\text{H}^6\text{Cl}^2$, formed, together with other products, by the action of chlorino on propane (p. 957), has the constitution $\text{CH}^3\text{—CHCl—CH}^2\text{Cl}$, and is convertible into ordinary propylene glycol, $\text{CH}^3\text{—CHOH—CH}^2\text{OH}$ (Schorlemmer).

Propylene Chlorohydrate, $(\text{C}^3\text{H}^6)^{\text{r}}\text{Cl}(\text{OH})$ or $\text{CH}^3\text{—CHOH—CH}^2\text{Cl}$, produced by direct combination of propylene with hypochlorous acid, is converted, by heating with potassium cyanide in sealed tubes, into the corresponding *cyanohydrate*, $(\text{C}^3\text{H}^6)^{\text{r}}\text{CyOH}$, and this latter boiled with caustic potash is converted into an acid, $\text{C}^3\text{H}^6\text{O}^2$, isomeric with oxybutyric acid:

(Markownikoff, *Zeitschr. f. Chem.* [2] iv. 620).

Bromo- and Chloro-propylenes.—Monobromopropylene, $\text{C}^3\text{H}^5\text{Br}$ (boiling at 56.5°, sp. gr. 1.408 at 19°), is converted by agitation with chlorino-water and mercuric oxide into monochloroacetone:

Monochloropropylene (b. p. 23°; sp. gr. 0.918 at 9°) is converted into chloracetone by similar treatment. Monobromo- or monochloro-propylene heated for several days to 100° with mercuric acetate and glacial acetic acid, is converted into acetone (Linneman, *Ann. Ch. Pharm.* cxxxviii. 122).

Chloropropylene, $\text{C}^3\text{H}^5\text{Cl}$, treated with concentrated sulphuric acid, yields hydrochloric acid and a sulpho-acid (containing the residue C^3H^4) which when distilled

with water yields acetone. Similar reactions are exhibited with sulphuric acid by amyl chloride, glycolic chlorhydrin, and benzyl chloride. Allyl chloride, on the other hand, which is isomeric with chloropropylene, unites directly with sulphuric acid (with partial carbonisation), and the product diluted with water yields by distillation in the water-bath a small quantity of propylene chloride, $C^3H^5Cl^2$ (formed by combination of allyl chloride with hydrochloric acid proceeding from the decomposition of another portion of that compound), and on further distillation, *propyl-glycol chlorhydrin*, C^3H^5ClO (b. p. $126^\circ-128^\circ$), separable from the distillate by potassium carbonate. This mode of formation shows that the constitution of propyl-glycol chlorhydrin must be represented by the formula $CH^3-CHOH-CH^2Cl$ (not by $CH^3-CHCl-CH^2OH$): for whatever may be the constitution of allyl chloride, the chlorine contained in it is united with the external and not with the middle chlorine-atom. Allyl chloride in contact with strong hydriodic acid is converted, with rise of temperature and evolution of iodine and hydrochloric acid, into isopropyl iodide, C^3H^7I . Chloropropylene, on the other hand, is easily converted by hydriodic acid into a slightly coloured heavy oil which decomposes by distillation even in a vacuum. The portion which passes over under a pressure of 1 centimetre between 100° and 130° consists of $C^3H^5Cl.HI$, or chloriodopropane, C^3H^5ClI . No chlorinated acetic acid compound can be obtained from this body by heating either with potassium acetate or with silver acetate. With silver benzoate there is formed, even at ordinary temperatures, a compound isomeric with propylene bibenzoate, which crystallises from ether in regular octohedrons and is resolved by water into benzoic acid and a liquid smelling of acetone.

Acetone is also produced when chloriodopropane is heated with moist silver oxide. Hence the chlorine, as well as the iodine, is united in this compound with the middle carbon-atom, and the reactions take place in the manner shown by the equations:

In the benzoic compound, the chlorine and iodine are replaced by 2 at. of the residue $C^7H^5O^2$; so that this compound, *dibenzopropane* or *dibenzodimethyl-methane*, $C^7H^5(C^7H^5O^2)_2$, may also be regarded as a compound of acetone with benzoic anhydride, $C^7H^5O.C^7H^5O^2$. It is called by Oppenheim *methyl-benz-acetol*, and the chloriodine compound, *methylido-chloracetol*, similarly to Friedel's *methyl-chloracetol* (p. 825). Chloriodopropane is distinguished from Simpson's propylene chloriodide, $C^3H^4.ClI$, obtained by the action of iodine chloride on propylene, by its specific gravity, which is 1.932, whereas that of propylene chloriodide is 1.834 at 0° , and by its behaviour with silver oxide. Another difference between chloropropylene and allyl chloride is afforded by their reaction with bromine. According to Friedel (*Ann. Ch. Pharm.* cxii. 236), chloropropylene bromide, $C^3H^5ClBr^2$ (boiling at 170°), treated with alcoholic potash gives up hydrochloric acid, and is converted into chlorobromopropylene, C^3H^4ClBr , which when heated for some time with potassium acetate and alcohol, forms propargylic ether, $C^3H^2(C^2H^5)O$ (p. 958). Allyl chloride, on the other hand, is converted by bromine, with vivid reaction, into allyl bromochloride, $C^3H^5ClBr^2$, a colourless liquid boiling at 195° , which when treated with potash does not yield pure brominated allyl chloride; by excess of alcoholic potash it is converted into propargylic ether. Hydrogen dioxide does not combine either with chloropropylene or with allyl chloride (Oppenheim, *Bull. Soc. Chim.* [2] x. 128; *Jahresh.* 1867, p. 569).

PROPYLENE-GLYCOL. $C^3H^5O^2$.—This diatomic alcohol may be formed, as shown by Lourenço (*Compt. rend.* lii. 1043), by the action of sodium-amalgam on monochlorhydrin, C^3H^5ClO , and converted by oxidation into ordinary lactic acid. Moreover, dichlorhydrin, $C^3H^4Cl^2O$, dissolved in ether free from alcohol but not dehydrated, is converted by sodium-amalgam into isopropyl alcohol, from which by oxidation acetone is produced. The relations between these several compounds may accordingly be represented by the following formulæ:

(Buff, *Ann. Ch. Pharm. Suppl.* v. 247).

PROPYL-METHYL CARBINOL. $\text{C}^3\text{H}^7 \cdot \text{CH}^3 \cdot \text{CHOH}$.—One of the modifications of secondary amyl alcohol (p. 111).

PROPYL-METHYL KETONE, $\text{CO} \left\{ \begin{array}{l} \text{C}^3\text{H}^7 \\ \text{CH}^3 \end{array} \right.$, is formed by treating 1 mol. butyryl chloride, $\text{COC}^3\text{H}^7\text{Cl}$, with 2 mol. zinc-methyl, and immediately subjecting the product to the action of water. It is a liquid which boils at 95° , and does not combine with sodium bisulphite. *Propyl-ethyl ketone*, $\text{CO} \left\{ \begin{array}{l} \text{C}^3\text{H}^7 \\ \text{C}^2\text{H}_5 \end{array} \right.$, formed in like manner with zinc-ethyl, boils at 115° , and is likewise incapable of forming a crystalline compound with sodium bisulphite. When the product of the action of zinc-methyl on an acid chloride is left for some days before it is treated with water, a tertiary alcohol is obtained instead of a ketone (Butlerow, pp. 115, 374).

PROPYLPHYCITE. $(\text{C}^3\text{H}^7)^3(\text{OH})^3$ (v. 893).—Details respecting the preparation of this compound from the corresponding bromodichlorhydrin, $\text{C}^3\text{H}^7\text{BrCl}^2(\text{OH})$, are given by J. Wolff (*Ann. Ch. Pharm.* cl. 28; *Zeitschr. f. Chem.* [2] v. 464). The same bromodichlorhydrin treated in alcoholic solution with potassium sulphhydrate, yields the potassium-salt of *disulphopropylphycite*:

On treating the resulting alcoholic solution with water, the potassium salt is resolved into potassium hydrate and disulphopropylphycite, $\text{C}^3\text{H}^7\text{O}^2\text{S}^2$ or $\text{C}^3\text{H}^7(\text{OH})^2(\text{SH})^2$, which is precipitated as a light-grey amorphous powder, insoluble in potash, ether, alcohol, water, and benzol, even at the boiling heat, but easily soluble in alcoholic solutions of alkaline sulphides. The alcoholic solution of the potassium salt yields with copper and mercury salts, precipitates of corresponding composition. *Disulphopropylphyctic acid*, $\text{C}^3\text{H}^7\text{S}^2\text{O}^4$, is formed by prolonged boiling of disulphopropylphycite with dilute nitric acid. Its *barium salt*, $\text{C}^3\text{H}^7\text{S}^2\text{O}^4\text{Ba}$, is amorphous, insoluble in alcohol, easily soluble in water, permanent in the air at 120° . The *cupric salt*, $\text{C}^3\text{H}^7\text{S}^2\text{O}^4\text{Cu}$, which is green and very hygroscopic, is converted by alcoholic ammonia into the cuprammonium salt, $\text{C}^3\text{H}^7\text{S}^2\text{O}^4(\text{N}^2\text{H}^4)_2$, which is deep blue by transmitted, almost black by reflected light, insoluble in alcohol, but soluble with blue colour in water (Wolff).

On the other hand, A. Claus (*Ann. Ch. Pharm.* cxlvi. 244; *Zeitschr. f. Chem.* [2] v. 670) denies the existence of propylphycite altogether. According to his experiments, propylphyctic acid (v. 894) is nothing but glyceric acid, and the so-called propylphycite is probably a glyceric aldehyde.

PROTAGON (iv. 737). According to Bacyer and Liebreich (*Arch. f. pathol. Anat.* xxxix. 183), protagon is a glucoside, yielding by its decomposition—besides considerable quantities of glucose, glyceric and phosphoric acid—a neurine-compound which crystallises in microscopic needles, and swells up in water. On the occurrence of protagon in the animal organism, see *Blood, Egg, Lecithine* (pp. 351, 458, 779).

PROTEIDS. (Syn. *Albuminoids*.)—This name has been given to a group of substances which form the chief mass of the nitrogenous material of animals and plants, and of which the albumin of the white of egg and the fibrin of blood may be taken as types.

They have never as yet been obtained in a crystalline form, and they exhibit very great instability of composition; accordingly our knowledge of their exact constitution is very meagre. It is true that hæmoglobin, the red colouring matter of the blood, which may frequently be obtained in a crystalline form, is capable of being split up into hæmatin and a proteid component; but this latter is by itself not crystallisable (Lehmann's statement to the contrary being apparently founded on error). Similarly, certain crystals in the yolk of eggs, in the seeds of plants, and in dried spermatie fluid appear to contain some proteid matter in combination with other substances; but these proteids have not as yet been isolated in a crystalline form.

Nearly all proteids when in aqueous solution or suspension are found to change in character, especially in their solubilities. These changes are very marked at a temperature of about 40°. The preparation of most of the substances is tedious, and hence the results of the examination of apparently the same substance vary exceedingly.

The compounds they form with metallic salts and other bodies are variable in composition (those with potassio-platinic cyanide no less than others) (Diakonow, *Hoppe-Seyler's Untersuch.* ii. p. 228).

They all contain nitrogen, carbon, hydrogen, oxygen (sulphur and phosphorus), in the proportions given below. That the sulphur in proteids is unoxidised is shown by their giving off sulphuretted hydrogen when treated with strong alkalis, and in various other decompositions. The phosphorus is probably present as phosphate, either mechanically attached or joined in some peculiar loose combination.

All proteid solutions are laevorotatory.

With one exception (peptones), all proteids diffuse with great difficulty.

Boiled with Millon's reagent* they all give a deposit which after a while turns red, the supernatant liquor also becoming coloured red. Heated with strong nitric acid they turn yellow, the mixture on addition of ammonia becoming a deep orange (xantho-proteid reaction).

They change the colour of the cupro-potassic test-liquid for sugar from blue to violet.

Proteids are very conveniently divided into classes as is done by Hoppe-Seyler (*Handbuch physiol. chem. Anal.*).

CLASS I. ALBUMINS.—Soluble in water.

1. Egg-albumin. *Preparation.*—The white of hen's egg is diluted with an equal bulk of water, well stirred, treated with dilute acetic acid as long as any precipitate falls, filtered, carefully neutralised, and concentrated to the original bulk at a low temperature.

Characters.—A neutral, transparent, generally faintly yellowish fluid, turning the plane of polarisation to the left, the specific rotation being 35.5° for yellow light (sodium flame). Heated to about 70° the whole or greater part of the substance is thrown down as a flocculent or curdy precipitate. The supernatant liquid, always more alkaline than before, is generally opalescent, from the formation of alkali-albumin (see below).

By careful acidulation all proteid matter is thrown down, and a perfectly clear filtrate obtained.

The substance thus thrown down is not a mere precipitate. It differs radically in its characters from soluble albumin, is remarkable by its great insolubility, and is called *coagulated albumin* (see below.)

The exact temperature at which this coagulation by heat takes place is much affected by various circumstances, notably by the presence of neutral salines, which lower the point of coagulation.

Treated with excess of alcohol, egg-albumin is wholly precipitated from its solutions. If the alcohol be rapidly filtered off, the precipitate may be wholly or in great part redissolved in water. Within a short time, however, it is found that, under the influence of the alcohol, the precipitate passes into the coagulated state; the longer the alcohol is allowed to act, the greater is the proportion of the material coagulated.

By strong mineral acids, especially by nitric acid, egg-albumin is precipitated and coagulated.

Metallic salts, such as mercuric chloride, silver nitrate, lead acetate, give a precipitate containing variable quantities of the precipitant. The lead precipitate suspended in water, treated with sulphydric acid to remove the lead, and neutralised, gives a solution of albumin. The white of egg always contains saline matters, which are retained in the solution of albumin prepared as above. All attempts completely to remove these salines by dialysis, &c., have failed, and it is still an open question whether they in part are in some way intimately associated with the albumin, and whether their presence is not essential to its being in a state of solution.

2. Serum-albumin. *Preparation.*—Serum of blood is diluted with water, treated with dilute acetic acid as long as any precipitate appears, filtered, neutralised, and reduced to its original bulk at a low temperature.

Characters.—Thus prepared, serum-albumin agrees in its main features with egg-albumin. They differ in the following points:

* *Millon's Reagent.*—Equal quantities of mercury and strong nitric acid are mixed and gently warmed till the mercury is dissolved. The solution is diluted with twice its bulk of water, and the copious precipitate allowed to settle. The clear supernatant liquid is the reagent.

The specific rotation of serum-albumin is 56° for yellow light.

Egg-albumin agitated with ether is coagulated. If the solution be dilute, the coagulum appears on standing at the junction of the two liquids. Serum-albumin is not coagulated by ether.

Egg-albumin is very readily coagulated by strong hydrochloric acid; the coagulum redissolves with very great difficulty. Serum-albumin is not so readily coagulated by the same acid; the coagulum redissolves readily.

CLASS II. GLOBULINS.—Insoluble in water, soluble in very dilute acids and alkalis, soluble in dilute (1 p. c.) solutions of sodium chloride and other neutral salts.

1. **Myosin.** *Preparation.*—Fresh muscle finely minced is rapidly washed with distilled water until the wash-water gives no signs of containing proteids or of being acid, and is then treated with a 10 or 5 p. c. solution of sodium chloride. The resulting viscid mass is strained through linen, filtered through coarse paper, and dropped little by little into a large quantity of distilled water. A large flaky precipitate is thus produced which settles on standing. The liquid is removed by decantation and filtration, the precipitate redissolved in the saline solution, filtered, and again precipitated with water.

Characters.—Insoluble in water. Readily soluble in sodium chloride solutions, of 1 to 10 or more p. c. (also in other neutral saline solutions). From these solutions myosin is precipitated either by extreme dilution or by saturation. On adding the solid salt to a sodium chloride solution of myosin, the liquid becomes more and more viscid, and just as the point of saturation is reached, the whole of the myosin is precipitated. The precipitate may then be separated by filtration, and washed if necessary with saturated solution of the salt. The amount of salt still adhering to it is sufficient to render it capable of being dissolved when treated with distilled water.

Treated either by the method of dilution or of saturation, the myosin remains unchanged by the action of the reagents.

Exposed, however, either in solution or suspension for any length of time, especially at a temperature of 20° – 40° , myosin changes in solubility, becoming less and less soluble in dilute neutral saline solutions. The same change may be brought about instantaneously by dilute acids or alkalis. Myosin is exceedingly soluble in dilute acids. The solutions are uncoagulated by boiling, indeed apparently unchanged. On neutralisation the whole of the proteid is thrown down; the acid solution is also precipitated by the addition of neutral salines. The precipitate, however, is no longer myosin; it is no longer soluble in dilute neutral saline solution; it has passed into Class III. In like manner myosin is extremely soluble in dilute alkalis; the whole of the dissolved proteid may be precipitated on neutralisation, but the precipitate is no longer soluble in dilute neutral salines; it too belongs to Class III.

Suspended in water and heated to 70° , myosin enters into the insoluble or coagulated condition. The neutral saline solutions of myosin are coagulated by heat.

Just as fibrin (see below) does not exist as such in living blood, so myosin does not exist as such in living muscle. It makes its appearance *pari passu* with the condition of muscle known as *rigor mortis* (of the mechanical phenomena of which it is most probably the cause), by a process similar to the coagulation of blood. If living, still irritable muscle, freed as much as possible from blood and lymph (the muscle of frog is most convenient for the purpose), be frozen, minced, mixed with snow containing 1 per cent. of sodium chloride, and powdered, at a temperature below freezing point, the mixture may with great care be filtered when melting. The filtrate speedily (at the temperature of the body almost immediately) sets into a gelatinous mass, which afterwards separates by contraction into a clot and serum. The clot, however, has the characters, not of fibrin, but of myosin.

2. **Globulin.** (*Paraglobulin.*) *Preparation.*—When fresh blood serum is diluted tenfold with water, and a brisk stream of carbonic acid passed through it, a fine granular precipitate is formed, which may be separated by decantation and filtration, and washed with water.

It may also be prepared by saturating blood-serum with sodium chloride (or magnesium sulphate, &c.), as in the case of myosin. A certain amount of the salt will cling to the precipitate.

Characters.—Globulin is exceedingly soluble in dilute saline solutions (from which it may be precipitated unchanged by carbonic acid gas or exceedingly dilute acids). Insoluble in water, it is dissolved however when the water is saturated with oxygen.

From its solution by oxygen it may be precipitated by carbonic acid, redissolved by oxygen, &c.

* In excessively dilute alkalis it is dissolved without change of characters; in dilute solutions, *e. g.*, of 1 p. c. it is soluble, with change, becoming converted into a member of Class III. By dilute acids, however feebly, it is changed on solution into a member of Class III. When suspended in water and heated to 70° it enters into the insoluble or coagulated condition, Class V.

From its solution in neutral salines it may be precipitated by saturation. The same solutions heated to 70° are coagulated.

Globulin is present, not only in serum of blood, but also in aqueous humour, in the juice of the cornea, connective tissue, &c. Derived from the former of these sources, globulin is fibrinoplastic, *i. e.* has the power of so acting in concert with certain fluids (fibrinogenous) as to give rise to fibrin (see below). The crystalline lens contains a substance which is not fibrinoplastic, but which in many other respects closely resembles the globulin thus described. It is stated (Hoppe), that its solutions with neutral salines are not precipitated on saturation, in this respect resembling vitellin. It has been proposed to reserve for the latter the name globulin, and to call the fibrinoplastic globulin, paraglobulin (Kühne, *Lehrb. Phys. Ch.*).

3. **Fibrinogen.** If hydrocele, pericardial, or other fluid capable of giving a clot with blood-serum or paraglobulin, be treated by the method adopted for globulin, a similar substance may be obtained, which resembles globulin in all particulars, except that the carbonic acid precipitate is more difficult to obtain, and more flaky, as of coarser grain, and that the body is more readily thrown down from the fluids in which it is found, by a mixture of alcohol and ether, and by the fact that it is fibrinogenous, *i. e.* requires to be mixed with fibrinoplastic globulin for the production of fibrin.

4. **Vitellin.** If the yolk of hen's egg be treated with ether, most fatty and colouring bodies are dissolved. There remains a white granular body which is insoluble in water, but readily soluble in neutral saline solutions. It is so much more soluble in these solutions than myosin, that it filters easily, and is not precipitated by saturation with the salt. Otherwise it has the characters of myosin, but is probably a more complex substance. It is neither fibrinoplastic nor fibrinogenous. By the action of dilute acids or alkalis, like the other members of this class, it passes on solution at once into the next class, III.

CLASS III. DERIVED ALBUMINS.—Insoluble in water; insoluble in sodium chloride solutions; soluble in dilute acids and alkalis.

1. **Acid-albumin.** If a small quantity of dilute acid (hydrochloric or acetic) be added to serum- or egg-albumin, no precipitation or coagulation takes place. On gradually raising the temperature of the mixture to 70°, it will be found that coagulation at that or at a higher temperature has been entirely prevented. At the same time the influence of the fluid on polarised light has been altered. The rotation to the left has become increased to 72°.

On carefully neutralising the cooled mixture, the whole of the proteid matter is thrown down as a white, flocculent, frequently gelatinous precipitate. The action of the acid has converted the albumin soluble in water into a substance insoluble in water. The precipitate is very readily soluble in excess of the alkali used for neutralisation, may be reprecipitated by again neutralising with an acid, again redissolved by excess, and so on. It is also soluble in dilute solutions of alkaline carbonates. It is insoluble in sodium chloride solutions, and may be precipitated from its solutions by the addition of their salt. Suspended in water and heated to 70°, it enters into the coagulated or insoluble condition.

This conversion of albumin into acid-albumin takes place with very great rapidity at such degrees of temperature as in the absence of an acid would coagulate the albumin. At lower temperatures the conversion takes place much less rapidly. If a mixture of albumin and acid be left at the ordinary temperature, and portions tested by neutralisation from time to time, it will be found that the neutralisation precipitate gradually increases, until at last the whole of the albumin is thus thrown down. This is the case equally with egg- or serum-albumin. The augmentation of the neutralisation precipitates takes place *pari passu* with changes in the effect on the polarised ray.

All the globulins of Class II. are readily soluble in dilute acids; by the act of solution they are however at once converted into acid-albumin, the neutralisation precipitate being no longer soluble in neutral saline solutions. Thus the myosin of thoroughly washed muscle may be at once extracted by dilute hydrochloric acid

(e.g. 1 p. c.) in the form of acid-albumin, long known as *syntonin*. No characters are at present known by which syntonin or acid-albumin derived from muscle may be distinguished from other forms of acid-albumin.

Like the globulins, acid-albumin changes rapidly in character when left exposed for any time to ordinary temperature. It becomes less and less soluble in dilute acids, requiring for its solution a stronger acid or an increase of temperature.

2. **Albuminate or Alkali-albumin.**—If egg- or serum-albumin be treated with dilute caustic alkali instead of with acid, coagulation by heat is similarly prevented, and the whole of the proteid may in like manner be thrown down on neutralisation.

Alkali-albumin may also be prepared from albumin by the action of strong caustic potash, according to the method of Lieberkühn.

White of egg is treated with an equal bulk of water, filtered, and reduced to its original volume by evaporation in shallow vessels at a low temperature. Potassium hydrate is then added drop by drop, until the mixture becomes a gelatinous transparent mass. This is cut into small pieces and washed rapidly until the wash-water ceases to have an alkaline reaction. It is then dissolved in hot water, giving an apparently neutral solution, from which it may be thrown down by the addition of a dilute acid. There is of course an immense loss of substance. Contact with oxygen is to be avoided.

Albuminate is insoluble in water and in solutions of sodium chloride, readily soluble in dilute acids, dilute alkalis, and dilute solutions of alkaline carbonates. In all these characters it agrees with acid-albumin. From its alkaline solutions it is precipitated by saturation with magnesium sulphate, and the precipitate is soluble in water. Its effect on the polarised ray is variable. Serum albumin treated with strong alkali acquires a rotatory power of 86° , egg-albumin 47° , coagulated albumin 58° , the result being nevertheless in each case albuminate.

Albuminate is insoluble in cold alcohol, and may be precipitated from its solution by an excess of that agent; in hot (diluted) alcohol it is however more or less soluble, the amount being very much increased by the presence of free alkali.

From its acid or alkaline solutions it is precipitated on neutralisation; in presence of sodium phosphate the alkaline solution has to be rendered freely acid before the precipitation takes place.

In these respects it differs from acid-albumin. These do not, however, appear very certain, and probably albuminate dissolved in dilute acid becomes acid-albumin, and acid-albumin in an alkaline solution becomes albuminate. Like acid-albumin, albuminate in acid or alkaline solution is unchanged by boiling; suspended in water, however, and heated to 70° , it passes into the coagulated state.

The proteid substance casein exists in milk. From this it may be thrown down by the addition of acetic acid, especially after dilution. The best results are obtained by adding a very small quantity of acetic acid until the first appearance of a precipitate, and then passing a brisk stream of carbonic acid through the mixture. The precipitate thus gained, when freed from fat, is insoluble in water and in sodium chloride solutions, but is readily soluble in dilute acids and alkalis (and alkaline carbonates), and reprecipitable on neutralisation. In fact, it agrees in most respects with albuminate. It may also be prepared from milk by saturating with magnesium sulphate, washing the precipitate free of fat, and redissolving in water.

Two facts are however brought forward to distinguish casein from albuminate:

1. When casein is treated with caustic potash, potassium sulphide is produced: this is not the case with albuminate.—2. Casein digested with artificial gastric juice yields a body containing phosphorus, whereas an albuminate which contains no phosphorus can be prepared from white of egg (Lubavin, *Hoppe-Seyler's med.-chem. Unters.* 1871, 463).*

Prepared by means of magnesium sulphate, casein has a rotatory power of 80° , in dilute alkaline solution of 76° , in strong alkaline solution of 91° , in dilute acid solution of 87° . Casein then may be taken as a naturally occurring alkali-albumin, just as syntonin is the most commonly and easily produced acid-albumin. A natural form of alkali-albumin also occurs in blood-serum (*serum casein* of Panum) and other similar fluids, besides the globulin and albumin. It may be obtained by adding dilute acetic acid to blood-serum freed by carbonic acid from globulin. A similar substance has been described as existing in the protoplasm of nerve-centres and in plain muscular fibre.

CLASS IV. Fibrin. Insoluble in water; with difficulty soluble in dilute acids and alkalis, and in neutral saline solutions.

* Lubavin's experiments seem also to show that casein, like vitellin or hæmoglobin, is a compound of an albuminous or proteid substance with a non-albuminous body.

This is the substance to which the clotting of blood is due. It may be obtained by washing blood-clots, or more readily by stirring with a bundle of twigs blood just shed, before it has had time to clot. The fibrin, which adheres in layers to the twigs, may then be stripped off and washed till perfectly white.

Fibrin differs from all the solid proteids in having a filamentous structure, and in possessing remarkable elasticity. It is insoluble in water at ordinary temperatures, passing into solution only at very high temperatures, or after very great length of time, and then becoming totally changed in its characters.

Treated with dilute hydrochloric acid, it swells up into a remarkably transparent mass, but resumes its natural appearance when the fluid is neutralised. At ordinary temperatures, the fibrin may remain subject to the action of the acid for days without sensibly passing into solution. At 50° to 60° it gradually dissolves, acid-albumin being formed.

In dilute alkalis it swells up to a less extent, and is more soluble in these than in dilute acids.

In neutral saline solutions (sodium chloride 5-10 p. c., potassium nitrate, &c.) it swells up to a viscid mass, and gradually dissolves, the solutions being coagulated by heat, the product being apparently a body of the globulin class.

Suspended in distilled water and heated to 70°, it shrinks, becomes more opaque, and loses its elasticity. Its solubilities are then identical with those of coagulated albumin. In the presence of an acid this coagulation takes place below 70°.

CLASS V. Coagulated Proteid. Insoluble in water, neutral saline solutions, dilute acids, and alkalis. On heating to 70° or thereabouts, egg- or serum-albumin in its natural solution, or any member of the globulins suspended in water or in solution in neutral salines, or any acid- or alkali-albumin, or fibrin suspended in water, coagulation takes place, and the product, as far as we know, has in all cases the same characters. It is insoluble in everything except the strong acids and alkalis, and even in these not always readily. One of the products of this method of solution is an acid- or alkali-albumin, as the case may be; there are also other products, probably many.

CLASS VI. Iardacein or Amyloid. In certain diseases there is deposited in the liver and elsewhere, a substance which, from its elementary composition and from the nature of the products of its decomposition, seems to be a proteid, and yet possesses certain unusual features. It resembles coagulated albumin in being insoluble in water, in dilute acid, alkali, and in neutral saline solution; it differs in completely resisting the action of gastric juice.

Its most notable character is the fact that it is coloured red or reddish-brown with iodine, violet or blue with iodine and sulphuric acid. This reaction has led to its being called amyloid; but it has no relation whatever to any of the starches, and by no treatment can sugar be got out of it. On the contrary, it is dissolved by concentrated hydrochloric acid, with formation of acid-albumin.

CLASS VII. Peptones. All proteid bodies (with the exception of iardacein) are converted, by the action of acid gastric or of alkaline pancreatic juice, into *peptones* (and other products). There are probably several peptones. Their general characters are extreme solubility and high diffusibility. They are not precipitated by acids, alkalis, or neutral salts, by acetic acid with ferrocyanide of potassium (at least, not all). They are precipitated by mercuric chloride and lead acetate. They are insoluble in alcohol and ether, but require for their precipitation from aqueous solutions a very great excess of alcohol. Their solutions are laevorotatory, and are not changed in this or in any other respects by boiling (as are all other proteid solutions). They are not in any way changed by the action of alcohol.

Peptones are produced from proteids by the action, not only of the above juices, but also by strong and especially by dilute acids, and by distilled water at high temperatures and pressure. Of the following bodies our knowledge is too incomplete to permit of any definite statement:

Meta-peptone. Dyspeptone.—Products observed by Meissner to occur in varying quantities in digestion experiments. The *parapeptone* of the same author seems to be nothing more than acid-albumin.

Metalbumin.—Observed by Scherer in a dropsical fluid. Precipitated by alcohol, but not coagulated; solution hardly coagulated by boiling; not precipitated by acetic or hydrochloric acid, or by acetic acid and potassium ferrocyanide.

Paralbumin.—A substance obtained by Scherer from ovarian cysts. The alkaline solutions are extremelyropy. It differs widely from proteids in elementary

composition (C 51·8, H 6·9, N 12·8, O 28·8, S 1·7), and besides contains, or is associated with, a body resembling glycogen, and capable of conversion into a substance with many of the reactions of sugar.

The relations of these various proteids may be tabulated thus:

Soluble in water:	
Aqueous solutions not coag. by boiling	PEPTONES.
Aq. sol. coag. by boiling	ALBUMINS.
Insoluble in water:	
Soluble in NaCl sol. 1 p. c.	GLOBULINS.
Insoluble	
Soluble in HCl, 1 p. c. in the cold:	
Soluble in hot spirit	ALKALI-ALBUMIN.
Insoluble "	ACID-ALBUMIN.
Insol. in HCl, 1 in the cold:	
Sol. in HCl, 1 p. c. at 60°	FIBRIN.
Insoluble in HCl, 1 p. c. at 60°; sol. in strong acids:	
• Sol. in gastric juice	COAGULATED ALBUMIN.
Insol. in gastric juice	AMYLOID.

The above method of solubilities is the only means at our command for distinguishing them. From their elementary composition we learn nothing, as may be gathered from the following table:

	C	H	N	O	S
Fibrin	52·6	7·0	17·4	21·8	1·2
Syntonin	51·1	7·3	16·1	21·5	1·1
Peptone	50·87	7·03	16·34	21·12	1·64
Albumin	51·37	7·13	19·00	23·12	2·12
Lardacein	53·6	7·0	15·0	23·1	1·3
In general from	52·7	6·9	15·4	20·9	·8
„ to	54·5	7·3	16·15	23·5	2·0

Many circumstances seem to point to the conclusion that undigested proteids are converted during digestion into peptones, by a process of cleavage, with assumption of water, analogous to that by which starch is converted into grape-sugar. And the fact that peptones of some kind or other are produced, not only by digestion, but also by ordinary chemical means, as the action of acids, &c., seems to point the same way. The various decompositions of peptone (and of the other proteids), especially that by pancreatic juice, indicate moreover that leucine and tyrosine are distinct elements in its structure; but other products appear to be invariably formed at the same time. Further than this we are at present unable to go.

A distinction may be drawn between 'natural' proteids, such as albumins, globulins, fibrin, and modified ones, such as acid- and alkali-albumin, which are produced by some actions (as of acid, &c.) on the former, either within or without the body. The great feature of all them is their instability. The most stable are the peptones and coagulated albumin, next come fibrin and albumin, then acid- and alkali-albumin, and, least stable of all, the globulins. So incessant are the changes they undergo, that it may be doubted whether they are fixed chemical compounds in the ordinary sense of that term.

For further details respecting proteids, see *Gmelin's Handbook*, xviii. 252-469.

M. F.

PROTocatechuic acid. $C^8H^6O^4$.—The formation of this acid, together with phloroglucin, by the action of melting potash on a variety of organic substances, is noticed under PHLOROGLUCIN (p. 928). It is also formed, together with acetic acid, by fusing caffeic acid with potash (Hlasiwetz, *Ann. Ch. Pharm.* cxlii. 219); by similar treatment of cinchona-red (Rombold, *ibid.* cxliii. 273); together with resorein and volatile fatty acids, by fusing asafetida with potash (Hlasiwetz a. Barth, *ibid.* cxxxviii. 81); and, together with pyrocatechin, by fusing sulphanisic acid with potash (Malin, *Ann. Ch. Pharm.* clii. 109).

A mixture of monobasic barium protocatechuate, $(C^8H^5O^4)^2Ba$, with saturated baryta-water, deposits after a while warty crusts of a tribasic salt, $(C^8H^5O^4)^3Ba^2$ (at 130°), analogous to the triplumbic salt obtained by Strecker (*iv.* 739).

Bromoprotocatechuic acid, $C^8H^5BrO^4$, obtained by triturating the acid with bromine,

and warming the product over the water-bath, crystallises from hot water in slender anhydrous rhombic needles, and when heated with a concentrated solution of 4 pts potassium hydrate to a pasty consistence, acidulated with sulphuric acid, and exhausted with ether, yields an acid crystallising in rhombic needles, and approximating in composition to gallic acid, $C^7H^4O^3 \cdot H^2O$. Protocatechuic acid is probably identical with carbohydroquinonic acid, inasmuch as these two acids agree in their reactions, melting point, and crystalline form, and when heated with hydriodic acid to 140° , yield, together with carbon dioxide, a mixture of hydroquinone and pyrocatechin (Barth, *Ann. Ch. Pharm.* cxlii. 246).

PROTOCATECHUIC ALDEHYDE, $C^7H^4O^3$, isomeric with oxybenzoic acid, is produced by heating dichloropiperonal with water (p. 948):

It is easily soluble in water, and crystallises from the concentrated solution mostly in concentric groups of flat crystals, which are best purified by recrystallisation from toluene. It melts and becomes dark-coloured at 150° , and decomposes at a higher temperature with separation of carbon. The aqueous solution mixed with ferric chloride acquires a very deep and pure green colour, changing to red on addition of a drop of solution of sodium carbonate. A similar reaction is exhibited by protocatechuic acid, but the green is not pure, inclining more to blue. The aldehyde is oxidised to protocatechuic acid by fusion with potash, also by permanganates. From ammoniacal silver-solution it throws down a silver speculum. It appears to unite with alkaline bisulphites, but without forming crystalline compounds (Rensen a. Fittig, *Zeitschr. f. Chem.* [2] vii. 100).

PSEUDO-ALCOHOLS. See ALCOHOLS (p. 65).

PSEUDOCUMENE. *Trimethyl-benzene.*—See BENZENE, HOMOLOGUES OF (p. 296).

PSEUDOCURCUMIN. See CURCUMIN (p. 517).

PSEUDOMORPHINE. $C^7H^{10}NO^4$ (O. Hesse, *Ann. Ch. Pharm.* cxli. 87).—This base, first noticed by Pelletier (iii. 1051), may be obtained in the preparation of morphine by Gregory's process, in the following manner. When the purified mixture of the hydrochlorides of morphine, codeine, &c., is mixed with a slight excess of ammonia, only the morphine is precipitated, and the filtrate, slightly supersaturated with hydrochloric acid, freed from alcohol, and somewhat decolorised by animal charcoal, yields, on neutralisation with dilute ammonia, a bulky precipitate, chiefly consisting of pseudomorphine. On washing this precipitate with water, dissolving it in acetic acid, and mixing the filtered solution with such a quantity of dilute ammonia that the supernatant liquid shall just slightly redden blue litmus-paper, only the pseudomorphine is precipitated, and may be purified by combining it with hydrochloric acid, and decomposing the recrystallised salt in hot aqueous solution with ammonia.

Pseudomorphine thus prepared is a finely crystalline white precipitate, having a silky lustre, and drying up to a dull white mass; when separated from a cold solution, it is gelatinous, and after prolonged drying, translucent and horny. It is insoluble in water, alcohol, ether, chloroform, carbon bisulphide, dilute sulphuric acid, and sodium carbonate, but dissolves easily in caustic alkalis and milk of lime. Aqueous ammonia dissolves it sparingly, but alcoholic ammonia dissolves it very easily when recently precipitated. Its solution in strong sulphuric acid is olive-green; the nitric acid solution has a deep orange-red colour, changing to yellow; the solution in ferric chloride is blue. The base and its salts are tasteless. The base dried at 120° has the composition $C^7H^{10}NO^4$; in the air-dried state it appears to contain 1 mol. water (5.6 p. c.). It is perhaps identical with Schutzenberger's oxymorphine (p. 841). The *hydrochloride*, $C^7H^{10}NO^4 \cdot HCl + H^2O$, is a white crystalline powder, insoluble in alcohol and dilute sulphuric acid, soluble in 70 pts. water at 20° ; the *platinochloride*, $2(C^7H^{10}NO^4 \cdot HCl) \cdot PtCl_4$, is a yellow amorphous precipitate. The *sulphate*, $2C^7H^{10}NO^4 \cdot H^2SO^4 + 6H^2O$, precipitated on mixing the hydrochloride with an equivalent quantity of sodium sulphate in slightly acidulated solution, forms small white laminae very much like gypsum. The *oxalate*, $2C^7H^{10}NO^4 \cdot C^2H^2O^4 + 6H^2O$, is a white precipitate composed of prismatic crystals; the *tartrate* forms sparingly soluble prisms; the *nitrate* shining laminae; the *chromate* a yellow crystalline precipitate; the *hydriodide* pale yellow prisms; the *aurochloride* a yellow amorphous precipitate; the *mercurochloride* a precipitate composed of colourless prisms.

PSEUDONEPHRITE. A calcio-aluminic silicate resembling nephrite, from Easton, described by A. Emmerling (*Jahrb. Min.* 1866, p. 558; *Jahresb.* 1866, p. 939).

PSEUDOSULPHOCYANATES. See SULPHOCYANATES.

PTEROLITE. A mineral occurring in the Brevig Sound in Norway, together with pitch-black mica, astrophyllite, wöhlerite, and agirip. It is massive and composed of numerous lamellæ, grouped like the beard of a feather and partly curved. Hardness = 2.5 to 3. Sp. gr. 3.063 to 3.666. Colour olive-green and liver-brown; lustre nacreous. Translucent only at the edges. An analysis by R. Müller gave

SiO ^a	Al ^a O ^a	CaO	MgO	K ^a O	Na ^a O	FeO	Fe ^a O ^a	H ^a O
39.38	6.65	5.47	0.56	7.86	2.81	16.43	19.89	1.39 = 100.44

(Breithaupt, *Jahrb. Min.* 1865, p. 858; *Jahresb.* 1865, p. 887).

PURPURIN. According to the recent investigations of Strecker (*Zeitschr. f. Chem.* [2] iv. 265), and of Graebe & Liebermann (*ibid.* 503), this substance has the composition of oxalazarin, C¹⁴H¹⁰O². For Böley's experiments on the composition of purpurin and other madder colours, see *Dingl. pol. J.* clxxxii. 351; *Jahresb.* 1866, p. 643. For E. Kopp's method of preparing purpurin, &c., from madder, see *Bull. Soc. industr. de Mulhouse*, xxxvii. 437; *Jahresb.* 1867, p. 955.

PURPURGALLIN. C²⁰H¹⁶O⁸ (A. Girard, *Compt. rend.* lxxix. 865; *Zeitschr. f. Chem.* [2] vi. 86).—A red colouring matter produced by oxidation of pyrogallie acid with silver nitrate in alcoholic solution, or more conveniently with permanganic acid. 60 grams of potassium permanganate are dissolved in a litre of water mixed with 55 grams of hydrogen sulphate, and this solution is gradually poured into a strong aqueous solution containing 40 grams of pyrogallie acid. Purpurgallin then separates in orange-red flocks, which may be purified by washing with a little water and crystallisation from alcohol, or by sublimation. It sublimes at about 200° in garnet-red needles, having a finer colour and stronger lustre than alizarin. It dissolves sparingly in water, more easily in alcohol, also in ether and in benzol, forming yellow solutions. Sulphuric acid dissolves it, forming a compound which crystallises in crimson needles decomposed by water. Most other acids dissolve it without alteration. Nitric acid attacks it energetically; the very concentrated acid may even set it on fire; ordinary nitric acid converts it into picric acid. Alkalis impart to the solutions of pyrogallin a transient blue colour; aluminium sulphate, on addition of ammonia, throws down a violet-blue lake, which gradually turns brown. Lead acetate forms a red-brown precipitate. Silver nitrate colours the solutions violet-blue, then brown, with separation of metallic silver. Auric chloride forms a bright carmine-red solution, which however also turns brown and deposits metallic gold. Purpurgallin dyes mordanted fabrics quickly and completely, but the colours are not very good.

PYRIDINE. C⁵H⁵N.—According to Chapman & Smith (*Ann. Ch. Pharm. Suppl.* vi. 329; *Jahresb.* 1868, 682), this base is formed by dehydration of amyl nitrite, e.g. when that compound is heated with phosphoric anhydride, C⁵H¹¹NO² = 3H²O = C⁵H⁵N.

Dipyridine. C¹⁰H⁸N² (Anderson, *Chem. Soc. J.* [2] vii. 406).—This base, polymeric with pyridine, is formed, together with other products, by the action of sodium on pyridine. When dry pyridine is heated to its boiling point with small pieces of sodium amounting to about one-fifth of its weight, in a flask furnished with a long condensing-tube, the whole is gradually converted into a dark brown or black mass, which solidifies on cooling to a hard brittle resin; and on separating this resin as completely as possible from unaltered sodium, and throwing it by small pieces into water, it is slowly converted into a thick brown oil, which collects at the bottom of the vessel, and when washed with water, dried with calcium chloride, and distilled in a current of hydrogen, yields at first a light oil consisting of several bases, then a thick heavy oil which deposits crystals of dipyridine. On redistilling this product, dipyridine crystallises in the neck of the retort, and the fluid portions of the distillate yield a further quantity of it when cooled by a freezing mixture. The formation of dipyridine by the action of sodium on pyridine takes place also in the cold. In this case, the sodium becomes covered, in the course of a few days, with a black brittle crust, which when washed with pyridine to remove an oil formed at the same time, then detached as completely as possible from the sodium, and thrown into water, yields a dark grey powder, which falls to the bottom. This powder washed till free from soda, and then spread out in contact with the air, is entirely converted into a snow-white mass of interlaced acicular crystals, consisting of dipyridine.

Dipyridine melts at 108°; solidifies to a crystalline mass on cooling; volatilises slowly at 100°; and sublimes unchanged at a high temperature, in long needle-shaped

Sup.

3 R

crystals. It dissolves rather sparingly in cold, but readily in boiling water, also in alcohol and ether, and separates in acicular crystals on cooling. It likewise dissolves in pyridine and in volatile oils. From the oily base with which it distils in the first process of preparation, it crystallises in short, thick, four-sided prisms, which are transparent so long as they remain in the liquid, but soon become opaque when removed from it. Dipyrindine is a very stable compound, not being decomposed by hydrochloric, sulphuric, or nitric acid. Potash and ammonia precipitate it from its solutions in acids as a mass of minute crystals. Its aqueous solution gives no precipitates with sulphate of magnesium, zinc, or nickel, with lead acetate, or with ferric chloride. With cupric sulphate it gives a pale bluish-white precipitate; with mercuric chloride a white amorphous powder insoluble in boiling water; and with silver nitrate a white precipitate insoluble in cold and sparingly soluble in boiling water, from which the compound is obtained in crystals on cooling. Its most characteristic reactions, however, are those it gives with ferro- and ferri-cyanide of potassium. When a few drops of potassium ferrocyanide are added to a not too dilute solution of dipyrindine hydrochloride, a pale precipitate makes its appearance, which rapidly changes to a dirty indigo colour, increasing at the same time in quantity. At a certain degree of concentration, the precipitate consists entirely of very minute needle-shaped crystals having a dark indigo colour, which dissolve in boiling water, forming a very deep and rather dull purple solution, and are again deposited on cooling; but if the boiling be continued for some time, the compound appears to undergo some change, for the liquid retains its red colour at ordinary temperatures, though a great part of the substance is still deposited in crystals. A saturated cold solution of dipyrindine in water gives no precipitate with potassium ferrocyanide; but on adding to the mixture a drop or two of hydrochloric acid, the dark precipitate instantly makes its appearance and is deposited in small crystals, easily soluble in hydrochloric acid. When potassium ferricyanide is added to dipyrindine hydrochloride, no immediate effect is observed; but on standing, the interior of the test-tube becomes lined with minute prisms, having a sulphur-yellow colour and strong lustre. On boiling, the solution acquires a dark colour, and partial decomposition takes place.

Dipyrindine gives by analysis the same percentage results as pyridine, C^5H^5N ; but its vapour-density, as found by experiment, is 5.92, agreeing nearly with that required by the formula $C^{10}H^{10}N^2$, viz. 5.46.

The salts of dipyrindine mostly crystallise well, but are not easily obtained of definite composition. The *hydrochloride*, $C^{10}H^{10}N^2 \cdot 2HCl$, forms flat needles, easily soluble in water, insoluble in ether. The *platinochloride*, $C^{10}H^{10}N^2 \cdot 2HCl \cdot PtCl^4$, is a yellow crystalline powder; the *palladio-chloride* an orange-coloured precipitate; the *zinc-chloride*, $C^{10}H^{10}N^2 \cdot 2HCl \cdot ZnCl^2$, crystallises in long white needles. The *sulphate*, $C^{10}H^{10}N^2 \cdot H_2SO^4$, separates from aqueous solution in needle-shaped crystals, which deliquesce in moist air. The *nitrate*, $C^{10}H^{10}N^2 \cdot 2HNO^3$, forms pale yellow needles, moderately soluble in water. On adding silver nitrate in excess to solution of dipyrindine hydrochloride, and immediately filtering from the precipitated silver chloride, the *argento-nitrate*, $C^{10}H^{10}N^2(HNO^3)^2 \cdot 2AgNO^3$, is deposited in sparingly soluble shining needles.

Dipyrindine Ethyl-iodide, $C^{10}H^{10}N^2 \cdot (C^2H^5I)^2$, is produced by heating dry dipyrindine with ethyl-iodide to 100° in sealed tubes. It forms needle-shaped crystals, brilliant and colourless if they have not been exposed to the air, very soluble in water, less soluble in alcohol and ether. Heated with silver chloride and water, it yields the corresponding chloride, which on addition of platonic chloride, yields the *ethyl-platinochloride*, $C^{10}H^{10}N^2 \cdot 2C^2H^5Cl \cdot PtCl^4$, in small sparingly soluble red needles. The base separated from the iodide by silver oxide—obviously an ammonium base—forms a highly alkaline solution, generally red or purple, which on evaporation leaves a dark uncrystallised residue.

Dibromo-dipyrindine, $C^{10}H^{10}Br^2N^2$, is precipitated on adding bromine to a solution of dipyrindine hydrochloride or hydrobromide, as a white powder, insoluble in water, slightly soluble in cold, more soluble in hot alcohol, from which it is deposited in flattened needles on cooling. It is very feebly basic and somewhat unstable.

The oily base formed, together with dipyrindine, as above described, appears to be a physical isomeride of dipyrindine; it boils at a somewhat lower temperature than the latter, undergoing partial decomposition at the same time.

The *light bases* formed when pyridine is heated with sodium (p. 977) contain more hydrogen than pyridine, and appear to be included in the general formula $C^mH^{2m-3}N$.

PYROAURITE. A ferric hydrate, containing magnesia, occurring in the serpentiniferous limestone at the Langbars iron mine in Sweden, forming white semi-translucent hexagonal tables, and containing 34.04 p. c. MgO , 23.92 Fe^2O^3 ,

34.56 H²O, and 7.24 CO² (= 99.76). The carbon dioxide must be regarded as an accidental admixture. The mineral is named pyroaurite on account of its property of acquiring a gold-colour in the fire (Igelström, *Jahresb.* 1867, p. 981).

PYROCATECHIN. The meta-modification of oxyphenol, C⁶H³O², produced: *a.* By the action of melting potash on meta-iodophenol. Ordinary iodophenol (produced by treating phenol with iodine and iodic acid) yields a mixture of hydroquinone and pyrocatechin (Körner, *Bull. Acad. Belg.* [2] xxiv. 166).—*β.* By the action of hydriodic acid on guajacol: C⁶H³O² + HI = C⁶H³I + C⁶H³O² (Gorup-Besanez, *Jahresb.* 1867, p. 688).—*γ.* By the dry distillation of protocatechuic acid, and, together with hydroquinone, benzoic acid, benzene, and phenol, by the dry distillation of quinic acid (Hlasiwetz a. Barth, *ibid.* 1864, p. 398, 405). It is also one of the products of the distillation of benzoïn (Hlasiwetz a. Barth, *Jahresb.* 1866, p. 574).

PYROGALLIC ACID. According to J. Personne (*Zeitschr. f. Chem.* [2] v. 728), this acid acts poisonously on the animal organism, in the same manner as phosphorus, namely by abstracting the oxygen of the blood.

Pyrogallie acid heated with picric acid and a little water unites with the picric acid, forming a compound which crystallises in large laminæ, and blackens slightly on exposure to the air (De Luynes, *ibid.* iv. 703). By oxidation with silver nitrate, permanganic acid, and other reagents, it yields purpuragallin (p. 977).

PYRO-ISOMALIC ACID. C⁶H⁴O³.—An acid produced by the action of heat on isomalic acid (p. 753).

PYRO-ITARACIC ACID. C⁶H⁴O³.—An acid formed by the dry distillation of itatartaric acid (p. 762).

PYROMUCIC ACID. C⁶H³O³ (Limpricht, *Zeitschr. f. Chem.* [2] v. 599).—For the preparation of this acid, Limpricht gives the preference to Ulrich's method of treating furfural with alcoholic potash (iv. 763); the product amounts to 33 p. c. of the furfural employed.

Pyromucic acid in aqueous solution is decomposed by bromine, yielding the compound C⁶H³O²; thus:

This acid is however immediately converted into the brominated acid, C⁶H³BrO², which distils over and solidifies in white feathery crystals, convertible by sodium-amalgam into a transparent liquid of low boiling point, having the composition C⁶H³O². The compound C⁶H³BrO² is converted by further action of the bromine into C⁶H³Br²O², which when treated with silver oxide, or when its aqueous solution is evaporated, exchanges its bromine for hydroxyl, and is converted into maleic or fumaric acid, C⁶H⁴O⁴. The dibrominated acid, C⁶H³Br²O², is still further converted by the free bromine into C⁶HBr³O², which also, when the solution is evaporated, exchanges 1 at. bromine for hydroxyl, and is converted into mucobromic acid, C⁶H³Br²O³ (iv. 763).

Limpricht regards the compounds of the pyromucic group as derivatives of the

PYROPHOSPHAMIC ACIDS. See PHOSPHAMIC ACIDS (p. 930).

PYROPHOSPHATES. See PHOSPHORIC ACIDS (p. 940).

PYRORACEMIC ACID. C⁶H³O³.—This acid is formed by gradually heating racemic acid in sealed tubes to 180° with hydrochloric acid (Geuther a. Riemann, *Zeitschr. f. Chem.* [2] v. 318). According to Wichelhaus (*Jahresb.* 1867, p. 403; further, *Ann. Ch. Pharm.* clii. 260), it does not exhibit the characters of an oxyacid. On mixing it with excess of phosphorus pentachloride, and heating the mixture to boiling after phosphorus oxychloride has been formed, then pouring it when cold into water, the water takes up ordinary pyroracemic acid (altered by boiling), which may be extracted from it by ether. Hence it appears that pyroracemic acid does not contain any alcoholic hydrogen. Wichelhaus represents it by the constitutional formula CH³—CO—CO²H, regarding it as homologous to carbacetylic acid and glyoxylic acid, (C²H³O²).

Pyroracemic is not reduced by hydriodic acid or attacked by acetyl chloride at the boiling heat. Pyroracemates subjected to dry distillation in contact with acetates yield acetone and pyrotartaric acid (Wichelhaus, *Zeitschr. f. Chem.* [2] v. 254).

Dry pyroracemic acid heated in a sealed tube with 1 mol. bromine is converted into dibromolactic acid, CH³Br—CBrOH—CO²H (Wislicenus, p. 771).

Bromopyraccemic acids (mono- and di-) are formed by heating pyraccemic acid to 100° in a sealed tube with 1 or 2 mol. bromine and water. The *dibrominated acid* is more easily obtained pure than the monobrominated acid, and may be extracted from the water by ether. It crystallises from aqueous solution in large rhombic tables, which contain $C^3H^2Br^2O^3 + H^2O$, and give off their 1 mol. water even on exposure to the air, more quickly in a vacuum. The effloresced acid crystallises from anhydrous solvents in long needles melting at 89°-91°. If the acid during its preparation be exposed for a long time to a high temperature, it is decomposed, with formation of pentabromacetone, C^3HBr^5O :

Dibromopyraccemic acid is decomposed by silver oxide, giving up all its bromine, and being converted in the cold, chiefly into mesoxalic acid, $C^2H^2O^3$; at a gentle heat silver is separated, and carbon dioxide is evolved. It is carbonised by alcoholic ammonia, but aqueous ammonia converts it into *imido-pyraccemic acid*, $CH(NH)-CO-CO^2H$. This compound possesses but slightly acid properties, and crystallises indistinctly; it unites directly with nitric acid, and gives with silver nitrate a white curdy precipitate, containing $C^3HAg(NH)O^3 \cdot AgNO^3$. *Monobromopyraccemic acid* has been obtained only as a syrupy liquid, which when treated with silver oxide, gives off carbon dioxide, as soon as the liquid becomes neutral, even at low temperatures. At a gentle heat silver acetate is produced (Wichelhaus, *loc. cit.*).

PYROTARTARIC ACID, $C^3H^3O^4$, is produced by heating pulverised tartaric acid to 180° in sealed tubes with hydrochloric acid (Guthrie, A. Riemann, *Zeitschr. f. Chem.* [2] v. 318); also, as above observed, by heating pyraccemates with acetates (Wichelhaus); also, together with several other products, by fusing gamboge with potash (Hlasiwetz, A. Barth, p. 628).

The *chloro-, bromo-, and iodo-derivatives* of pyrotartaric acid are formed, not from that acid itself, but by direct addition of Br^2 , Cl^2 , I^2 , or of HBr , HCl , HI , to the pyrocitric acids, $C^3H^3O^4$, and they exhibit different modifications, accordingly as they are formed from citraconic, itaconic, or mesaconic acid. (See ACIDS, ORGANIC, p. 49.) The dibromo-compounds, obtained by addition of bromine to these acids, were discovered by Kekulé, and are described in vol. iv. pp. 773, 774. The monochlorinated, monobrominated, and monoiodated derivatives have been studied by Swarts (*Bull. Acad. Belg.* [2] xvii. xix.; *Instit.* 1865, p. 23; 1866, pp. 323, 358; *Jahresh.* 1865, p. 392; 1866, p. 404); they are formed by addition of HCl , HBr , and HI , to itaconic, citraconic, and mesaconic acid respectively.

Citramonochloropyrotartaric acid, $C^3H^2ClO^4$, formed by heating citraconic anhydride to 120° for two or three hours with an equal volume of strong hydrochloric acid, crystallises from ether in nacreous laminae unctuous to the touch. Both in the dry state and in solution it is decomposed by the slightest elevation of temperature into hydrochloric and mesaconic acids. Heated with bases, it is resolved, like citra-dibromopyrotartaric acid, into carbon dioxide and crotonic acid:

In cold water it dissolves without decomposition, and the solution is not precipitated by silver nitrate; but on gently heating it, a precipitate of silver chloride is formed.

Itamonochloropyrotartaric acid is formed by heating pulverised tartaric acid to about 130° for three hours with 2 pts. of very strong hydrochloric acid, washing the product with cold water, and recrystallising from water or alcohol. It forms white lustreless nodules or crystals, like those of pyrotartaric acid, inodorous, and having an agreeable sour taste. It melts at 140°-145°, remaining liquid for a long time, and boils at 225°-230°, forming water, hydrochloric acid, and an oily anhydride which crystallises after a while, and is reconverted into the original acid. Heated to 150° in a stream of dry air, it gives off water, and leaves the anhydride, which, however, cannot be obtained pure, in consequence of simultaneous loss of hydrochloric acid. Hot water converts it into itamalic acid (p. 761):

The same decomposition is produced by strong bases; but the solution saturated with ammonia deposits sal-ammoniac on evaporation, and the mother-liquor contains mesaconic acid. Treated with silver oxide, it yields, together with silver chloride, the silver salt of paraconic acid, isomeric with itaconic acid, but monobasic (p. 760). *Ethylic itachloropyrotartarate*, $C^3H^2Cl(C^2H^5)^2O^4$, is obtained, by saturating the alcoholic solution of the acid with hydrochloric acid gas, and rectifying the liquid precipitated by water, as a colourless bitter liquid, which boils at 250°-252°, with formation of a small quantity of hydrochloric acid.

Mesamono-chloropyrotartaric acid is formed by repeatedly heating mesaconic acid to 160° with very strong hydrochloric acid. The solution of the product deposits on evaporation, first lustreless nodules of unaltered mesaconic acid, then small shining crystals of the much more soluble chlorinated acid. The latter melts at 129° – 130° , and is resolved by boiling with water into hydrochloric and mesaconic acids. It is converted by bases into crotonic acid.

Itadichloropyrotartaric acid, $C^3H^2Cl^2O^4$, formed by addition of chlorine to itaconic acid, is very soluble, forms large crystals, and is decomposed by boiling its solution.

Itamono-bromopyrotartaric acid, $C^3H^3BrO^4$, is prepared, like the chlorinated acid, by heating itaconic acid for half an hour to 160° with concentrated hydrobromic acid; also, though less advantageously, by the action of bromine on pyrotartaric acid at 120° ; also by the action of fuming hydrobromic acid on itamalic acid: $C^3H^3O^3 + HBr = H^2O + C^3H^3BrO^4$. It melts at 130° – 134° , remaining liquid for a long time, and boils without decomposition at about 250° . It is less easily decomposed by boiling water than the chlorinated acids, and reacts exactly like the latter with bases. *Ethyl itabromopyrotartate* is obtained by heating the acid with alcohol to 110° ; the product precipitated by water boils, with partial decomposition, at 270° – 275° .

Itamonoiodopyrotartaric acid, $C^3H^3IO^4$, is prepared by heating itaconic acid somewhat in excess with hydriodic acid to 150° in an atmosphere of carbon dioxide: if an excess of hydriodic acid be used, pyrotartaric acid will be likewise formed. The liquid purified from free iodine by treatment with mercury, deposits, on evaporation over sulphuric acid, dull nodular groups of crystals of the iodated acid (mixed with a little itaconic acid), which become colourless by repeated crystallisation from water. They melt at 135° , and decompose at 185° , with evolution of iodine. Boiling water produces only slow decomposition. The acid heated with hydriodic acid is reduced to pyrotartaric acid, with separation of iodine. Heated with alcohol containing hydrochloric acid, it yields ethylic itamono-iodopyrotartate.

Citra-iodopyrotartaric acid cannot be isolated. When citraconic anhydride is heated with fuming hydriodic acid, a brown crystalline mass separates on cooling, which when submitted to purification, is resolved into hydriodic and mesaconic acids. Since however pyrotartaric acid is obtained by continued heating of citraconic anhydride with fuming hydriodic acid, it may be supposed that citra-iodopyrotartaric acid is formed as an intermediate product.

PYROTARTARIC ACID. $C^3H^3O^3$ (Wislicenus a. Stadnicki, *Ann. Ch. Pharm.* cxlvi. 306).—A crystalline acid formed, together with pyrotartaric acid, by the dry distillation of tartaric acid: $3C^4H^4O^6 = C^3H^3O^3 + 5CO^2 + 5H^2O$. It is obtained most abundantly by somewhat rapid distillation, but always in very small quantity, not exceeding 0.02 p. c. To separate it, the products distilling between 120° and 180° are subjected to repeated fractional distillation. Nearly pure pyrotartaric acid is then obtained between 160° and 170° , and between 180° and 210° , a series of gradually diminishing fractions, which as they cool partly deposit the pyrotartaric acid in needle-shaped crystals. On dissolving these products in boiling water, whereby the admixed pyrotartaric anhydride is converted into pyrotartaric acid, and filtering at the boiling heat through wetted filters, the pyrotartaric acid separates on cooling in yellowish needles, which may be purified by recrystallisation from boiling water with addition of animal charcoal. Pyrotartaric acid crystallises from the mother-liquors.

Pyrotartaric acid forms colourless shining needles, soluble in about 400 pts. of boiling water, less soluble in cold water, easily soluble in alcohol and ether, and crystallising from the latter in short thick prisms. The solutions have a decided acid reaction. The acid melts at 134.5° , sublimes even below this temperature, in small needles, and easily passes over with vapour of water. The pyrotartarates of the alkali-metals are easily soluble in water; probably also those of the alkaline-earth metals. The lead and silver salts are white precipitates, insoluble in water, and becoming crystalline when immersed therein.

The acid treated with phosphorus pentachloride is converted into the chloride $C^3H^3O^2Cl$, which, however, is immediately reconverted by water into pyrotartaric acid. Wislicenus and Stadnicki regard this acid as a ketonic acid, $C^3H^3-CO-COOH$, although no hydrogen can be introduced into it by the action of sodium-amalgam. From its properties it might rather be supposed to belong to the aromatic group.

PYRRENE. See AUGRE.

PYRROL. C^4H^5N . This compound may be prepared by heating ammonium mucate with glycerin in a retort to 180° – 200° , the resolution of the ammonium salt

into pyrrol and ammonium carbonate then proceeding more regularly than by distillation. Silver oxide is reduced by pyrrol, with formation of a sublimable, easily soluble acid, which forms sparingly soluble compounds with silver and lead (Goldschmidt, *Zeitschr. f. Chem.* [2] iii. 280). The body thus formed reduces silver oxide almost as strongly as pyrrol itself: hence it is probable that the oxidation of pyrrol by silver oxide might be carried much further (Lubavin).

Sodium acts but slightly on pyrrol; but potassium acts very strongly, with great rise of temperature and evolution of gas, forming a thick, nearly colourless liquid, which solidifies in the crystalline form on cooling, and probably consists of potassium-pyrrol, C^4H^4KN , inasmuch as, when treated with water, it yields unaltered pyrrol, and is converted by ethyl iodide into ethyl-pyrrol. The latter may be prepared by gradually adding 1 at. potassium and 1 mol. pyrrol to a mixture of pyrrol with 5 to 7 parts of ethyl iodide in a flask with upright condenser, assisting the action by a gentle heat, afterwards removing the excess of ethyl iodide by distillation in a water-bath, and distilling in an oil-bath. The resulting liquid subjected to fractional distillation yields ethyl-pyrrol between 155° and 175° . Ethyl-pyrrol is a colourless liquid, soon however turning yellow and red. It has a peculiar turpentine-like odour, quite different from the ethereal odour of pyrrol. It is not perceptibly soluble in water, but floats upon it as an oil; becomes resinised by contact with air or by heating. It dissolves in hydrochloric acid, with copious evolution of white fumes, forming a dark red liquid, which does not deposit any solid substance on boiling, whereas pyrrol when heated with hydrochloric acid, becomes quite solid, from formation of pyrrol-red. Potash added to the solution boiled with hydrochloric acid, throws down an amorphous substance. The vapours of ethyl-pyrrol colour a deal-shaving moistened with hydrochloric acid red, just like pyrrol itself (Lubavin, *Zeitschr. f. Chem.* [2] v. 399).

Q

QUERCITRIN and **QUERCETIN**. Rochleder a. Kawalier have obtained quercitrin from the fully-developed leaves of the horse-chestnut, by fractionally precipitating the extract with basic lead acetate. Separated from the lead salt and dried at 100° in a vacuum, it gave by analysis numbers agreeing with the formula $C^{32}H^{50}O^{17}$, with 1, 2, 2½, and 3 mol. H^2O . The quercetin produced from it was composed of $C^{27}H^{42}O^{12} + H^2O$ (*Wien. Akad. Ber.* lv. [2] 46; *Jahresh.* 1867, p. 731). According to Rochleder (*loc. cit.* p. 211), the yellow colouring matter of the stem-bark of the apple-tree consists of hydrated quercetin having the same composition. Gintl (*Zeitschr. f. Chem.* [2] iv. 732) has found quercetin in the leaves of the ash-tree gathered towards the end of spring.

QUINIC ACID. $C^8H^{12}O^6$. This acid occurs, together with rubichloric acid and a small quantity of citric acid, in the herb of *Galium Mollugo* (F. Oehren, *Zeitschr. f. Chem.* [v] iii. 28).

Quinic acid treated with 5 mol. phosphorus pentachloride yields chlorobenzoyl chloride, together with phosphorus oxychloride and hydrochloric acid:

By fusion with 4 pts. potassium-hydrate it is converted into carbohydroquinonic acid:

(Graebe, *Ann. Ch. Pharm.* cxxviii. 197).

QUINIDINE. $C^{20}H^{21}N^2O^2$.—This base, isomeric with quinine, is, according to De Vrij (*Pharm. J. Trans.* xvi. 401), identical with the base first described in 1833 by Henry a. Delondre (*J. Pharm.* [2] xix. 623) as crystallised quinine-hydrate, and with the β -quinine obtained by Van Heijningen (*Jahresh.* 1849, p. 371) from commercial quinoïdine (v. 26).

F. Koch, on the other hand (*N. Jahrb. Pharm.* xxii. 240; *Jahresh.* 1864, p. 444), regards the base usually called quinidine as distinct from β -quinine, the latter according to his observations, occurring in all cinchona-barks, especially in Pitayo bark, the former in Carthagena, less frequently in Pitayo, never in Calisaya bark; but the differences do not appear to be very well made out.

De Vrij (*Jahresb.* 1866, p. 473) finds quinidine (or β -quinine) in all samples of commercial quinoïdine; but in consequence of the presence of a substance which accompanies it in the extracts and interferes with its crystallisation, it can in many cases be made to crystallise only by mixing the oxalic acid solution of quinoïdine, concentrated by evaporation, with a saturated solution of potassium iodide, and cautiously adding small quantities of alcohol of 80 p. c. till the milky turbidity produced by the potassium iodide has disappeared, and the viscid precipitate has redissolved. The hydriodide of quinidine then separates after a while as a sandy crystalline powder, especially after prolonged stirring with a glass rod.

According to van der Burg (*Zeitschr. anal. Chem.* iv. 273; *Jahresb.* 1865, p. 438), 1 pt. of quinidine dissolves at 19° in 80-90 pts. of ether.

Neutral aqueous solutions of hydrochloride and sulphate of quinidine give with potassium iodide a white amorphous precipitate, which separates in the crystalline state from solution in boiling water, and is sparingly soluble in alcohol. Acid solutions of quinidine salts mixed with potassium iodide gradually deposit the acid hydriodide in yellow or light red microscopic crystalline tufts. Respecting the estimation of quinidine by potassium iodide, see CINCHONA-BARKS (p. 461).

Platinosocyanide of Quinidine, $2(C^{20}H^{24}N^2O^2 \cdot HCl) \cdot PtCy^2 + 3H^2O$, is amorphous, dissolves in 2273 pts. water at 20°, in 91 pts. at 100°; in less than 3.5 pts. of alcohol (sp. gr. 0.8 at 16°), and in all proportions at the boiling heat. The acid platinosocyanide, $C^{20}H^{24}N^2O^2 \cdot 2HCl \cdot PtCy^2$, is crystalline; dissolves in 1923 pts. water at 19.5°, in less than 4 pts. at 100°; in 2353 pts. of the same alcohol at 17°, and in 1371 pts. at the boiling heat. Both these salts are insoluble in dilute sulphuric acid (Van der Burg).

QUININE. $C^{20}H^{24}N^2O^2$. The solubility in water of anhydrous quinine and of the trihydrate have been determined by F. Sestini (*Zeitschr. anal. Chem.* vi. 359):

	c. c. Water	
	at 20°	at 100°
1 grm. of Anhydrous Quinine, $C^{20}H^{24}N^2O^2$, dissolves in	1667	1428
1 grm. of the Hydrate, $C^{20}H^{24}N^2O^2 + 3H^2O$ „	902.5	773.4

Although quinine is somewhat soluble in moderately concentrated solutions of caustic potash or soda, its solubility in water is nevertheless diminished by the presence of alkalis, especially of soda: hence in the process of preparation it is advisable to precipitate the base with soda (Sestini). According to van der Burg (*Jahresb.* 1865, p. 438), 1 pt. quinine dissolves at 22° in about 23 pts. ether (sp. gr. 0.72 at 18°). When quinine is separated from the aqueous solutions of its salts by caustic soda, and the liquid is shaken up with ether, the quinine dissolves in a smaller quantity of ether (12.5 pts.). Quinidine and cinchonine, on the other hand, show but little increase of solubility under these circumstances. But a mixture of quinine, quinidine, and cinchonine exhibits different relations of solubility, the quantity of ether required to dissolve the cinchonine not being sufficient to take up the quinine and quinidine in addition.

For the estimation of quinine, Sestini evaporates the solution of a quinine salt in water acidulated with sulphuric acid, to dryness with sodium carbonate; washes the residue with water; dries the residual base at 100°, and weighs it. The quantity of quinine dissolved in the wash-water is ascertained by treating the evaporated residue with alcohol, again evaporating the filtrate in a platinum dish, and igniting the residue previously dried at 100° and weighed. Respecting van der Burg's method of estimating quinine in barks, see CINCHONA-BARKS (p. 461); for Körner's method of estimating the quantities of other cinchona-bases in commercial quinine, founded on the different degrees of solubility of the free bases and their sulphates in aqueous ammonia, see *Zeitschr. f. Chem.* i. 150; *Jahresb.* 1862, p. 619.

The amorphous precipitate formed by ammonia in solutions of quinine salts is anhydrous at first, but quickly changes, especially in presence of free ammonia, into the crystalline trihydrate $C^{20}H^{24}N^2O^2 + 3H^2O$, consisting of four-sided prisms terminated with domes, distinguishable by a lens. This hydrate gives off its water (14.2 p. c.) over sulphuric acid; dissolves in an equal weight of ether at 10°; melts at 57°; anhydrous quinine at 176.8° (Hesse, *Ann. Ch. Pharm.* cxxxv. 325; *Jahresb.* 1865, p. 441).

The following quinine salts have been examined by Hesse:

Hydrochloride,	$C^{20}H^{24}N^2O^2 \cdot HCl + 2H^2O$,	long asbestos-like prisms; anhydrous at 120° ; sol. in 39.4 pts. water at 10° .
Dihydriodide,	$C^{20}H^{24}N^2O^2 \cdot 2HI + 5H^2O$,	prisms and laminæ; anhyd. at 120° .
Benzoate,	$C^{20}H^{24}N^2O^2 \cdot C^6H^5O^2$,	small prisms, sol. in 373 pts. water at 10° .
Eugenato,	$C^{20}H^{24}N^2O^2 \cdot C^{10}H^{12}O^2$,	long silky prisms, melting to an oil in boiling water; soluble in 12 pts. ether at 10° ; melting, with loss of acid, at 110° .
Oxalates,	$2C^{20}H^{24}N^2O^2 \cdot C^2H^2O^4 + 6H^2O$,	long prisms; efflorescent; sol. in 1030 pts. water at 10° .
	$C^{20}H^{24}N^2O^2 \cdot C^2H^2O^4 + H^2O$,	small prisms, easily soluble in cold water.
Succinate,	$C^{20}H^{24}N^2O^2 \cdot C^4H^4O^4 + 8H^2O$,	long white prisms, easily sol. in hot water or alcohol; sol. in 1030 pts. water at 10° .
Citrates,	$2C^{20}H^{24}N^2O^2 \cdot C^6H^8O^7 + 7H^2O$,	prisms, sol. in 930 pts. water at 12° .
	$C^{20}H^{24}N^2O^2 \cdot C^6H^8O^7$,	prisms, slightly sol. in water.
Phosphato,	$2C^{20}H^{24}N^2O^2 \cdot PH^3O^4 + 8H^2O$,	tufts of long needles, sol. in 784 pts. water at 10° .
Arsenate,	$2C^{20}H^{24}N^2O^2 \cdot AsH^3O^4 + 8H^2O$,	long prisms, easily soluble in hot, sparingly in cold water.

Zinco-chlorides.—An alcoholic solution of quinine mixed with zinc chloride, and then with sufficient hydrochloric acid to redissolve the precipitate, deposits flattened prisms of the double salt $2(C^{20}H^{24}N^2O^2 \cdot 2HCl) \cdot ZnCl^2 + 2H^2O$. A solution of this salt in dilute sulphuric acid, or a hot alcoholic solution of acid quinine hydrochloride mixed with zinc chloride, yields the salt $2(C^{20}H^{24}N^2O^2 \cdot 3HCl) \cdot ZnCl^2 + 3H^2O$, which is easily soluble, and crystallises in wavelitic groups (Gräfinhoff, *Bull. Soc. Chim.* [2] iv. 391).

According to R. Hauer (*Zeitschr. f. Chem.* [2] i. 481), Herapath's sulphate of iodoquinine (v. 25) has, when dried over sulphuric acid, the composition $4C^{20}H^{24}N^2O^2 \cdot 3H^2SO^4 \cdot I^2 + 3H^2O$, and gives off its water (2.24 p. c.) at 100° in a stream of air. Quinine acetate likewise forms a crystallisable compound with iodine.

A very dilute solution of quinine mixed with about 3 mol. hydrochloric acid and 3 mol. potassium iodide, and left to itself in a loosely covered vessel, deposits crystals of the compound $4C^{20}H^{24}N^2O^2 \cdot 3HCl \cdot 3HI \cdot I^2$. Herapath's salt may be obtained in a similar manner. A warm alcoholic solution of *methyl-quinine hydriodide*, mixed with a sufficient quantity of iodine and left to cool slowly, deposits black prisms of *methyl-quinine tri-iodide*, $C^{20}H^{23}(CH^3)N^2O^2 \cdot III^2$. An isomorphous compound of ethyl-quinine is obtained in a similar manner (Jørgensen, *Zeitschr. f. Chem.* [2] v. 674).

Platinosocyanides.—The neutral salt, $2(C^{20}H^{24}N^2O^2 \cdot HCy) \cdot PtCy^2 + 2H^2O$, is obtained by adding platinous cyanide to a warm solution of neutral quinine sulphate, as an amorphous precipitate, melting with decomposition at 150° – 160° to a light brown liquid; not sensibly soluble in dilute hydrochloric acid. The acid salt, $C^{20}H^{24}N^2O^2 \cdot 2HCy \cdot PtCy^2 + 2H^2O$, obtained in like manner with acid quinine sulphate, forms microscopic tabular striated crystals, which cannot be dehydrated without decomposition, and are but slightly soluble in dilute acids. Of alcohol of sp. gr. 0.8 at 16° , the neutral salt dissolves in less than 5 pts. at 18° , and in all proportions at the boiling heat; the acid salt in 1270 pts. at 19° , and in 834 pts. at the boiling heat. Of water, the neutral salt dissolves in 1852 pts. at 18° , and in 56.5 pts. at 100° ; the acid salt in 1351.3 pts. at 18.5° , and in 20 pts. at 100° (van der Burg, *Jahresb.* 1865, p. 440).

A compound of quinine and *phenol*, $C^{20}H^{24}N^2O^2 \cdot C^6H^5O$, is obtained by gradually adding an alcoholic solution of 8.72 pts. quinine sulphate to an alcoholic solution of 3 pts. potassium phenate, filtering after 24 hours, and evaporating at a gentle heat. It forms beautiful crystals, easily soluble in alcohol and acids, nearly insoluble in water and ether (Romei, *Zeitschr. f. Chem.* [2] v. 383).

Dihydroxyl-quinine, $C^{20}H^{26}N^2O^4 = C^{20}H^{24}N^2O^2 \cdot (HO)^2 = C^{20}H^{24}N^2O^2 + H^2O + O$ (Kerner, *Zeitschr. f. Chem.* [2] v. 593).—A compound produced by treating quinine with potassium permanganate in quantity not sufficient to produce complete oxidation. When about 1 pt. of the permanganate is used to 2 pts. of quinine, about a third part of the quinine is converted into dihydroxyl-quinine, while another portion remains unaltered, and a third portion is converted into ammonia, carbon dioxide, and greasy resinous products rich in carbon. It is also formed in the passage of quinine through the animal organism, being found in small quantity in the urine.

Dihydroxyl-quinine crystallised from water with addition of animal charcoal forms small, hard, colourless prisms having a vitreous lustre; from alcohol it crystallises in long, silky needles. The crystals contain $C^{20}H^{26}N^2O^4 \cdot 3H^2O$. It dissolves but sparingly in water and in alcohol, more freely in presence of free alkali or of a large quantity of a strong acid; in very dilute acids, on the contrary, it is less soluble than in pure water. It is tasteless and neutral to vegetable colours, but resembles the alkaloids in being precipitated from aqueous and acid solution by tannic acid, potassium di-iodide, potassio-mercuric iodide, and platinic chloride, and from aqueous, acid, and alcoholic solutions by the phosphometallic acids of molybdenum, tungsten, antimony, and vanadium. It exhibits a blue fluorescence in nitric acid solution, and produces with chlorine-water and ammonia a green colour similar to that obtained with quinine. Potassium permanganate attacks it but slowly in the cold and in alkaline solution; but when heated in acid solution with excess of permanganate, it is completely oxidised. Its solutions are coloured brown, like those of quinine, by prolonged exposure to the sun.

QUINONE and HYDROQUINONE. Graebe (*Zeitschr. f. Chem.* [2] 478) represents quinone, tetrachloroquinone (chloranil), and hydroquinone by the following formulæ:

which indicate that in quinone and tetrachloroquinone the two oxygen-atoms are united together by one of their affinities, thereby constituting a bivalent group, whereas in hydroquinone this association is broken up by the entrance of the hydrogen. The same relation holds good between chloranilic and hydrochloranilic acid:

This mode of viewing the constitution of quinone explains the circumstance that when quinone is acted upon by chlorine, the ultimate product is not C^6Cl^4 , but only hex-chlorobenzene, C^6Cl^6 , together with free chlorine.

Of the three modifications of oxyphenol, $C^6H^4O^2$, hydroquinone, pyrocatechin, and resorcin, hydroquinone is the only one which is convertible into a compound containing 2 at. hydrogen less, viz. quinone. Hence it appears most probable that in hydroquinone the two hydroxyl-groups are attached to contiguous carbon-atoms, so that the developed formulæ of quinone and hydroquinone are:

Hydroquinone.

Quinone.

Hydroquinone is accordingly ortho-oxyphenol (1 : 2), whereas in pyrocatechin and resorcin the two hydroxyl-groups occupy the relative positions 1 : 3 and 1 : 4.

In tetrachloroquinone two of the chlorine-atoms are easily replaceable by OH, NH^2 , and SO^2H , giving rise to such compounds as chloranilamide or dichloramidiquinone, $C^6Cl^2(NH^2)^2(O^2)^2$, chloranilic acid or dichloramidoxiquinone, $C^6Cl^2(NH^2)(OH)(O^2)^2$, &c. These replaceable chlorine-atoms appear to be the two which are nearest to the two connected oxygen-atoms: for Graebe has shown, by comparison of a large number of known examples, that a chlorine-atom joined to a carbon-atom is most easily replaceable when the same carbon-atom is also united with oxygen, or connected with another carbon-atom having oxygen attached to it.

Brominated Quinones.

Tetrabromoquinone or Bromanil. $C^6Br^4O^2$.—To prepare this compound, a weighed quantity of bromine is introduced, together with $\frac{1}{2}$ pt. iodine and 5 pts. cold water, into a flask closed with a good cork through which passes a long tube, and a

quantity of phenol equal to $\frac{1}{15}$ the weight of the bromine is slowly poured in through the tube. A violent reaction takes place, and the vessel becomes very hot. The phenol adhering to the sides of the tube is then washed down with 5 pts. more of water, and the whole is heated to 100° for an hour or two. After cooling, the semi-solid contents of the flask are collected on a filter, freed from mother-liquor as completely as possible by means of a Bunsen's pump (p. 617), and digested once or twice in the cold with carbon bisulphide, to remove tribromophenol formed at the same time. The tetrabromoquinone then remains in crystalline scales, very much like tetrachloroquinone, which are purified by treating them once or twice with boiling alcohol, and recrystallising from benzol (Stenhouse, *Chem. Soc. J.* [2] viii. 9).

Aniline added in excess to a solution of bromanil in hot benzol, forms bromanil-phenylamide, $(C^6H^5)(C^6Br^2O^2)H^2N^2$, in nearly black, crystalline laminae, which may be purified by washing with boiling alcohol (Stenhouse).

Bromanilic acid, $C^6Br^2\left\{\begin{smallmatrix} (O^2)^* \\ (OH)^2 \end{smallmatrix}\right.$, is prepared like chloranilic acid, which it resembles. Nitric acid converts it into bromopicricin and oxalic acid. With alkaline sulphites, it yields salts of disulphodibromhydroquinonic acid, $C^6\left\{\begin{smallmatrix} (OH)^2 \\ Br^2 \\ (SO^2H)^2 \end{smallmatrix}\right.$, and thionic acid, $C^6\left\{\begin{smallmatrix} OH \\ (SO^2H)O \\ (SO^2H)^2 \end{smallmatrix}\right.$. With sulphurous acid, however, it does not appear to yield

the acid corresponding to Koch's hydrochloranilic acid.

When 3 pts. bromine are gradually added, with stirring, to 1 pt. bromanilic acid suspended in 8 pts. cold water, the acid dissolves, forming a yellow liquid, which after 24–48 hours, deposits crystals of the compound $C^6Br^{11}HO$, which, when recrystallised from carbon bisulphide, forms colourless, transparent prisms melting at 110.5° , easily soluble in ether, carbon bisulphide, and benzol, and dissolving in alcohol with decomposition.

Tetrabromhydroquinone or **Bromhydranil**, $C^6H^2Br^4O^2$, is formed by the action of aqueous sulphurous acid on bromanil, but considerable loss arises from the formation of secondary products. The theoretical quantity of bromhydranil may, however, be obtained by digesting bromanil with hydriodic acid and phosphorus.

Tribromhydroquinone, $C^6H^3Br^3O^2$, is formed, together with the preceding compound, when sulphurous acid gas is passed through boiling water in which bromanil is suspended; it remains in solution, and may be separated with lead carbonate, and purified in the same manner as trichlorhydroquinone (p. 987); the product is however but small. It resembles trichlorhydroquinone in its physical properties.

When the preceding solution was evaporated, and then mixed with potassium chromate and sulphuric acid, a brownish-yellow precipitate was formed, which, after recrystallisation from dilute alcohol, exhibited the composition of tribromoquinone, $C^6HBr^3O^2$ (Stenhouse, *loc. cit.*).

Chlorinated Quinones and Hydroquinones.

(Carius, *Ann. Ch. Pharm.* cxliii. 316; *Zeitschr. f. Chem.* [2] iv. 17; *Jahresb.* 1867, p. 644. Koch, *Zeitschr. ibid.* 202; *Jahresb.* 1867, p. 646. Graebe, *Ann. Ch. Pharm.* cxlvi. 1. *Zeitschr. ibid.* 464; *Jahresb.* 1867, p. 649. Stenhouse, *Chem. Soc. J.* [2] vi. 141; viii. 6).

Dichloroquinone, $C^6H^2Cl^2O^2$, is produced by the action of chlorous anhydride on benzene. On distilling the liquid, after a considerable quantity of the gas has been passed into it, benzene passes over first, then chlorobenzene, and the residue, boiling above 135° solidifies almost wholly to crystals of dichloroquinone. The first product of the action is probably dichlorohydroquinone, which, by the further action of the chlorous anhydride and the benzene, is converted into chlorobenzene and dichloroquinone:

Dichloroquinone is more easily obtained, together with chlorobenzene and trichlorophenomalic acid (p. 917), by dissolving 48 grms. benzene in 300 grms. strong sulphuric acid, in loosely stoppered flasks, diluting with 150 grms. water, adding 100 grms. benzene after cooling, and then gradually adding 150 grms. potassium chlorate. At a

temperature of 18° to 20° , the reaction is completed in a week. The flasks are then heated by immersion in water to 60° - 70° ; water is added in sufficient quantity to dissolve the potassium sulphate; and the supernatant benzene solution is separated by a pipette from the watery liquid, washed with water to remove trichlorophenomalic acid, and subjected to fractional distillation. The dichloroquinone may be extracted from the residue by hot alcohol, and crystallises therefrom in deep yellow, strongly lustrous, short prisms and tables, often joined together by their acuter summits. In very dilute solution it is quickly decomposed by potash or baryta, the liquid acquiring a deep green, or, if excess of alkali is present, a brown colour. The change appears to consist in the formation of dichlorhydroquinone, together with a very unstable chlorinated acid not yet examined:

When dichloroquinone is heated with saturated baryta-water, in the proportion of $\text{C}^6\text{H}^2\text{Cl}^2\text{O}^2$ to BaH^2O^2 , and the baryta precipitated by sulphuric acid, dichlorhydroquinone may be extracted from the filtrate by ether, together with a humus-like substance, whilst the aqueous solution retains a small quantity of an easily soluble amorphous acid (Carius).

Trichloroquinone, $\text{C}^6\text{HCl}^3\text{O}^2$, is produced, together with tetrachloroquinone, by gradually adding a mixture of 1 pt. crystallised phenol and 4 pts. potassium chlorate to gently warmed hydrochloric acid diluted with an equal bulk of water, then adding more potassium chlorate by small portions till the separated crystals have turned yellow, washing these crystals with cold water, and finally digesting them with cold alcohol, as long as this liquid acquires a yellow colour. This product (as also that obtained in like manner from phenylsulphuric acid or from salicin, v. 29) is a mixture of tri- and tetra-chloroquinone in about equal quantities. These two compounds cannot be separated by crystallisation from alcohol, but their separation is easily effected by first converting them into the corresponding hydroquinones. For this purpose the crystalline mass is suspended in water and saturated with sulphurous acid, then left to itself for 24 hours, heated to boiling when it has become colourless, and the residue is repeatedly boiled with water, which takes up the greater part of the trichlorhydroquinone, leaving the tetrachlorhydroquinone mixed with a small quantity of trichlorhydroquinone. The trichlorhydroquinone separates from the solution in large crystals. On slowly dropping nitric acid into the hot filtrate, nitrogen dioxide is given off, and trichloroquinone immediately separates in yellow crystals. The same treatment may be advantageously applied to the mother-liquor of the crystallised trichlorhydroquinone (ferric chloride may also be used as the oxidising agent instead of nitric acid). The tetrachlorhydroquinone is purified by recrystallisation from alcohol, acetic acid, or benzol, but still retains a small quantity of trichlorhydroquinone, which adheres to it obstinately. By treatment with nitric acid, or with potassium chlorate and hydrochloric acid, it is converted into tetrachloroquinone (Graebe). On the preparation and purification of these products, see also Stenhouse (*Chem. Soc. J.* [2] vi. 208).

Trichloroquinone prepared as above agrees in all its properties with that which Städeler obtained (v. 28) from quinic acid (melting point 164° to 166° ; Städeler found 160°). Dilute potash colours it green and then dissolves it with red-brown colour, forming chloranilic acid, the potassium salt of which separates after a while in needles:

Phosphorus pentachloride does not act on trichloroquinone under ordinary pressure; but on heating the mixture to 180° - 200° in a sealed tube, with addition of phosphorus oxychloride, the trichloroquinone is converted into perchlorobenzene, according to the equation:

With **acetyl chloride**, trichloroquinone forms diacetyl-tetrachlorhydroquinone:

Trichlorhydroquinone, $\text{C}^6\text{H}^3\text{Cl}^3\text{O}^2$, prepared as above, crystallises in large shining prisms, which become turbid in contact with the air. It melts at 134° (at 130° according to Städeler, iii. 216), dissolves sparingly in cold water, more easily in hot water (in which it first melts), very easily in alcohol and in ether. The aqueous solution gradually turns brown in contact with the air, from formation of hexachloroquinhydrone. Lead acetate throws down from it the lead salt, $\text{C}^6\text{HCl}^3\text{O}^2\text{Pb}$, which dissolves easily in acetic acid, and turns brown when exposed to the air in the most

state. With potash-ley trichlorhydroquinone reacts in the same manner as trichlorquinone. Heated in sealed tubes with potassium hydrate and ethyl-iodide, it yields the ethylic ether, $C^6Cl^3H(C^2H^3O)^2$, which, when purified by distillation or by recrystallisation from alcohol, forms long needles melting at 68.5° , and agreeing in its reactions with the ethylic ether of tetrachlorhydroquinone (*infra*). Diacetyl-trichlorhydroquinone, $C^6Cl^3H(C^2H^3O^2)^2$, is obtained like the corresponding compound of tetrachlorhydroquinone, from which it differs by its greater solubility in alcohol and ether. It melts at 153° and sublimes in colourless needles.

Trichlorhydroquinone is converted by oxidising agents into trichloroquinone, or by incomplete oxidation into hexchlorquinhydrone, $C^{12}Cl^6H^4O^4$, which (especially when cold nitric acid is used) crystallises in long black needles. Trichlorhydroquinone heated with 2 mol. phosphorus pentachloride is converted into penta- and hex-chloro benzene. On the other hand, it does not appear possible to replace the chlorine in this compound by nascent hydrogen (treatment with sodium-amalgam), only small quantities of dichlorhydroquinone appearing to be thereby produced (Graebe).

Trichlorobromoquinone, $C^6Cl^3BrO^2$, is formed by heating trichlorhydroquinone with bromine to 120° for some hours in a sealed tube. After washing with water, it dissolves very sparingly in hot alcohol, from which it crystallises in yellow tables on cooling.

Trichlorobromhydroquinone, $C^6Cl^3BrH^2O^2$, obtained by digesting the preceding compound with hydriodic acid and phosphorus, is easily soluble in alcohol, crystallises therefrom in long prisms, and is reconverted into trichlorobromoquinone by boiling with nitric acid (Stenhouse).

Tetrachloroquinone or Chloranil, $C^6Cl^4O^2$, is formed by heating potassium chloranilate with 2 mol. phosphorus pentachloride (Koch):

Respecting its preparation and purification, see page 987. It may also be prepared by the prolonged action of iodine chloride on phenol in presence of water. The resulting crystalline mass yields a quantity of chloranil equal to half the weight of the phenol employed (Stenhouse, *Chem. Soc. J.* [2] viii. 6). Heated to 180° with PCl^5 , it is decomposed, with formation of $POCl^3$ and carbonaceous products. A more definite reaction takes place on addition of the oxychloride. A mixture of 1 pt. tetrachloroquinone, $2\frac{1}{2}$ pts. PCl^5 , and $2\frac{1}{2}$ pts. $POCl^3$, heated for two or three hours to 180° – 200° , yields hexchlorobenzene, C^6Cl^6 , crystallising in long yellow needles:

Tetrachlorhydroquinone or Chlorhydranil, $C^6Cl^4H^2O^2$.—The hydrogen in this compound may be replaced by metals or organic radicles. The salt which crystallises from its solution in potash-ley, is supposed by Graebe to have the composition $C^6Cl^4(KO)^2$, but is too unstable to be prepared in the pure state.

Diethyl-tetrachlorhydroquinone, $C^6Cl^4(C^2H^3O)^2$, is produced by heating 2 mol. potassium hydrate, rather more than 2 mol. ethyl iodide, and an equal quantity of alcohol to 130° – 140° for two or three hours, and may be isolated by treating the evaporated filtrate with water, and purified by recrystallisation from ether. It crystallises in colourless needles which melt at 112° , sublime without decomposition, are insoluble in water, dissolve sparingly in cold alcohol, but easily in boiling alcohol and ether. It is not attacked by boiling potash-ley, and is dissolved without decomposition by fuming nitric acid, and reprecipitated by water. Heated with hydriodic acid to 130° – 140° , it is reconverted into tetrachlorhydroquinone and ethyl iodide.

Diacetyl-tetrachlorhydroquinone, $C^6Cl^4(C^2H^3O^2)^2$, is formed by the action of acetyl-chloride on tetrachlorhydroquinone at ordinary temperatures:

The action is completed by gentle heating with excess of acetyl chloride; the latter is then distilled off, and the product is purified by washing with water and soda-ley, and final sublimation. The same compound is obtained by the action of acetyl chloride on trichloroquinone (p. 987). It forms colourless shining needles, melting at 245° , insoluble in water, slightly soluble in cold alcohol and ether, abundantly in boiling alcohol. With potash-ley and cold nitric acid, it reacts like the ethyl-compound; hot fuming nitric acid breaks up the acetyl-groups and converts the compound into tetrachloroquinone (Graebe).

Dichlorodioxiquinone or Chloranillic Acid. $C^6Cl^2H^2O^4 = C^6Cl^2 \left\{ \begin{smallmatrix} (O^2)^2 \\ (OH)^2 \end{smallmatrix} \right.$

Dichloroquinoylic Acid (v. 34).—The potassium salt of this acid is prepared by adding

chloranil moistened with alcohol, to very dilute potash-ley (containing 1 p. c. potassium hydrate) heated to about 50°, and agitating as long as anything is taken up; the liquid is then filtered warm, evaporated to one half, and strong potash-ley is added to it by drops till a quickly cooled sample solidifies in crystals. The salt then crystallises after a few hours in beautiful purple-red prisms, and the remainder may be separated from the mother-liquor by evaporation and passage of carbon dioxide (Graebe); see also Stenhouse (*Chem. Soc. J.* [2] viii. 6).

Chloranilic acid heated with sp. gr. 1.45 yields oxalic acid and a distillate of chloropierin. By chlorine, or more quickly by iodine-chloride in presence of water, it is converted into oxalic acid and a heavy oil. The acid suspended in water is converted by bromine into a white crystalline body, having the composition $C^6Br^2C^4H^2O$. This compound dissolves easily in carbon bisulphide, and crystallises therefrom by spontaneous evaporation in very large prisms. In alcohol it dissolves with decomposition, the solution when evaporated, even at ordinary temperatures, giving off alcohol, and leaving an oil. It dissolves easily in benzol and in ether, melts at 79.6°, and distils without decomposition. It does not appear to be attacked by boiling sulphuric acid (Stenhouse).

Ethyl Chloranilate, $C^6Cl^2(C^2H^3)^2O^4$, obtained by decomposing silver chloranilate with ethyl iodide, crystallises in smooth bright red prisms, melting at 107°, soluble in benzol, light American oil, carbon bisulphide, and ether, moderately soluble in alcohol, somewhat soluble in boiling water (Stenhouse).

Hydrochloranilic Acid or Dichlorotetrahydroxybenzene. $C^6Cl^2H^4O^4 = C^6Cl^2(HO)^4$ (Koch; Graebe, *loc. cit.*).—This compound is produced by the action of reducing agents on chloranilic acid, as when sodium-amalgam is gradually added to a solution of the latter acid, or its potassium salt, kept slightly acid by addition of hydrochloric acid, till the liquid is decolorised and hydrogen begins to escape. Hydrochloranilic acid then crystallises out, and may be purified by washing with water, pressing between paper, and drying over sulphuric acid in a vacuum. The reduction may also be effected by tin and hydrochloric acid, or by heating chloranilic acid to 100° for several hours in a sealed tube with saturated aqueous sulphurous acid. When the liquid has become colourless and cold, the tube is opened, the excess of sulphurous acid removed by a current of carbonic acid gas, and the solution is left to crystallise out of contact with the air (Koch). Graebe regards this last mode of preparation as the best.

Hydrochloranilic acid forms colourless needles easily soluble in water, alcohol, and ether, inodorous, having a burning taste, and slight acid reaction. It is permanent in the dry state, but when moist is easily oxidised to chloranilic acid by the action of air, chlorine, or bromine. With alkalis it forms solutions which are colourless at first, but turn red on exposure to the air, and gradually deposit a salt of chloranilic acid. The solution of the acid quickly reduces silver nitrate, and forms with barium chloride and cupric sulphate, on addition of ammonia, green precipitates, which quickly turn brown on exposure to the air.

Hydrochloranilic Chloride. $C^6Cl^2\left\{ \begin{smallmatrix} Cl^2 \\ (HO)^2 \end{smallmatrix} \right.$ —When 1 mol. hydrochloranilic acid is heated with 2 mol. phosphorus pentachloride, hydrochloric acid and phosphorus oxychloride are given off, and the partially carbonised residue yields with water a yellow solution which deposits hydrochloranilic chloride in colourless needles. This compound, isomeric with tetrachlorhydroquinone, is formed as shown by the equation:

It is more permanent than the acid, dissolves with yellow colour in water and alcohol, and may be recrystallised without decomposition. It is distinguished from tetrachlorhydroquinone by its easy solubility in water. Its solutions slowly decompose, with formation of chloranilic acid, and are coloured dark green by ferric chloride. Heated to 100° in a stream of dry chlorine, it is converted, with evolution of hydrochloric acid and a volatile strong-smelling oil, into a red unctuous mass, which hardens in a vacuum over quick lime, but quickly deliquesces in the air, and dissolves with red colour in water. Silver nitrate throws down from this solution a brown crystalline precipitate, $C^6Cl^4Ag^2O^4$, which is permanent in dry air, and detonates when quickly heated. The product formed by the action of chlorine appears therefore to be *dichloro-hydrochloranilic acid*, $C^6Cl^4H^2O^4$; by water and by bases at the boiling heat it is quickly converted into chloranilic acid (Koch).

Tetraceto-hydrochloranilic acid, or Dichloro-tetracetoxybenzene, $C^6Cl^2(C^2H^3O^2)^4$, is formed by heating hydrochloranilic acid with acetyl chloride to 100° in a sealed tube. On expelling the excess of acetyl chloride on the water-bath, washing the resulting crystals with water, and recrystallising from alcohol, the dichlorotetracetoxybenzene

separates in colourless needles, insoluble in water, slightly soluble in cold alcohol and ether, more easily in boiling alcohol. It sublimes without decomposition in needles, melts at 235° , and is very stable, not being attacked by weak oxidising agents, or by cold potash-ley. Boiling potash slowly converts it into chloranilate and acetate of potassium. Koch's hydrochloranilic chloride is regarded by Graebe as tetrachlorinated substitution-product of pyrocatechin or resorcin.

Tetrachlorotetroxyquinhydrone, $C^{12}Cl^4H^2O^8$, is formed by the incomplete reduction of chloranilic acid by sulphurous acid, or when hydrochloranilic acid is oxidised on exposure to the air. It crystallises in slender black needles; is converted by oxidation into chloranilic acid, and by further treatment with sulphurous acid into hydrochloranilic acid (Graebe).

Sulpho-acids derived from the Chlorinated Quinones and Hydroquinones.

The salt described by Hesse (v. 22) as potassium disulphodichlorosalicylate is according to Graebe's analysis, the potassium salt of *dichlorhydroquinone-disulphuric acid*, $C^6Cl^2S^2H^2K^2O^8$. It is produced by adding tetrachloroquinone to a warm dilute solution of acid potassium sulphite:

Thiochronic Acid. $C^6H^4S^2O^{17}$.—The potassium salt of this acid, which Hesse obtained by the action of acid potassium sulphite on tetrachloroquinone, is conveniently prepared, according to Graebe, by saturating a slightly warmed dilute solution of neutral potassium sulphite with tetrachloroquinone, separating the yellow crystals which are deposited on cooling, from the lighter white crystals of the preceding salt formed at the same time, finally recrystallising it from water, and boiling it with alcohol to remove the last portions of the white salt. The air-dried thiochronate has the composition $C^6HS^2K^2O^{17} + 4H^2O$, and gives off 3 mol. water, at 130° . In its formation, the chlorine of the tetrachloroquinone is replaced by the group SO^3K , and the resulting compound, $C^6 \begin{Bmatrix} O^2 \\ (SO^3K)^2 \end{Bmatrix}$, unites with 1 mol. acid potassium sulphite,

forming the thiochronate, $C^6 \begin{Bmatrix} OH \\ O(SO^3K) \\ (SO^3K)^4 \end{Bmatrix}$. Heated with water in a sealed tube, it is resolved into *hydroquinone-disulphate* and acid sulphate of potassium, according to the equation:

The crystallised salt undergoes the same decomposition when quickly heated to 100° , and in dilute hydrochloric solution even at 100° . The hydroquinone-disulphate is also produced from the thiochronate, together with acid sulphite, by the action of reducing agents, as by boiling the solution with zinc-dust, or treating it with sodium-amalgam and hydrochloric acid. The attempt to prepare other salts of thiochronic acid was not successful.

Euthiochronic acid, produced by the action of alkalis on thiochronic acid, and regarded by Hesse (*Ann. Ch. Pharm.* cxiv. 292) as $C^6H^4S^2O^8$, by Greiff (*Jahresb.* 1863, p. 392) as $C^6H^4S^2O^{10}$, is, according to Graebe, *dioryquinone-disulphuric acid*,

The formation of the potassium salt by the action of potash on the thiochronate, or on the dichlorhydroquinone-disulphate (in the latter case with aid of atmospheric oxygen), is represented by the following equations:

Free euthiochronic acid is obtained by exactly decomposing the barium salt with sulphuric acid, and evaporating the solution, finally over strong sulphuric acid, and crystallises in yellow needles easily soluble in alcohol and ether. The following salts have been examined :

Hydro-euthiochronic or *Tetroxybenzene-disulphuric acid*, $\text{C}^6\text{H}^4\text{S}_2\text{O}^{10}$ = $\text{C}^6\left\{\begin{array}{l} (\text{OH})^4 \\ (\text{SO}^2\text{H})^2 \end{array}\right\}$, is produced by the action of reducing agents on outhiochronic acid. The potassium salt, $\text{C}^6\text{H}^4\text{S}_2\text{O}^{10}\text{K}^2 + 2\text{H}_2\text{O}$, is obtained, by boiling the outhiochronate with tin and hydrochloric acid, till the solution is decolorised, and evaporating the filtrate, in colourless prisms, which in the moist state quickly turn red by oxidation. It is slightly soluble in cold, more easily in hot water, forming a solution which oxidises in the air in presence of free alkali, reduces silver nitrate in the cold and mercurous nitrate at the boiling heat, forming a salt which crystallises in red needles; ferric chloride colours the solution dark brown-red. The sodium salt, $\text{C}^6\text{H}^4\text{S}_2\text{O}^{10}\text{Na}^2 + 2\text{H}_2\text{O}$, is prepared in like manner, and exhibits similar characters.

Hydroquinone-disulphuric Acid, $\text{C}^6(\text{OH})^2\text{H}^2(\text{SO}^2\text{H})^2$.—This acid, produced, as above mentioned, from thiochronic acid by heating with water or hydrochloric acid, is different from that which Hesse obtained by treating quinic salt with sulphuric acid (iii. 217). Graebe distinguishes this latter as α , and the acid produced from thiochronic acid as β hydroquinone-disulphuric acid. The free β acid is obtained by precipitating the potassium salt with lead acetate, decomposing the precipitate with hydrogen sulphide, and evaporating the filtrate to a syrup over sulphuric acid. It crystallises in deliquescent tables, easily soluble in alcohol, insoluble in ether. Its strongly acid solution is coloured blue by ferric chloride. The potassium salt, $\text{C}^6\text{H}^4\text{S}_2\text{O}^{10}\text{K}^2 + 4\text{H}_2\text{O}$, separates from the hot aqueous solution in large prisms, with oblique end-faces; gives off its crystallisation-water over sulphuric acid; dissolves very easily in hot, very sparingly in cold water, and is insoluble in alcohol. The solution has a neutral reaction, is coloured deep blue by ferric chloride; is not precipitated by barium or calcium chloride, and with aid of heat reduces mercuric to mercurous chloride, silver nitrate and mercurous nitrate to metal.

Trichlorhydroquinone-sulphuric Acid, $\text{C}^6\left\{\begin{array}{l} (\text{OH})^2 \\ \text{Cl}^3 \\ \text{SO}^2\text{H} \end{array}\right\}$.—The potassium salt

of this acid, $\text{C}^6(\text{OH})^2\text{Cl}^3\text{SO}^2\text{K} + \text{H}_2\text{O}$, is formed, together with euthiochronate, by dissolving trichloroquinone in neutral potassium sulphite, and separates in colourless microscopic crystals. It reacts like the potassium salt of the preceding acid, but is soluble in alcohol. The solution mixed with potash turns red in contact with the air, and gradually deposits the potassium-salt of monochloro-dioxyquinone-sulphuric acid. The free trichlorinated acid, $\text{C}^6\text{H}^2\text{Cl}^3\text{SO}^2$, prepared like the preceding acid from the lead salt, crystallises in deliquescent needles easily soluble in alcohol and ether.

Potassium Monochlorodioxyquinone-sulphate, $\text{C}^6\text{ClSO}^2\text{K}^1 + 2\text{H}_2\text{O}$, crystallises from a solution of potassium trichlorhydroquinone-sulphate mixed with potash and exposed to the air, in red needles, while yellow-brown salts formed at the same time, but not yet examined, remain in the mother-liquor. It is easily soluble in water, both hot and cold, less soluble in alkaline liquids, insoluble in alcohol. Calcium chloride added to the aqueous solution throws down a red-violet precipitate. Hydrochloric acid added to the concentrated solution throws down the acid salt $\text{C}^6\text{ClH}^2\text{SO}^2\text{K}$ as a crystalline precipitate, which dissolves with blood-red colour in water, and crystallises from the hot-saturated solution in yellow laminae. By tin and hydrochloric acid the neutral salt is reduced to a colourless compound not yet examined (Graebe).

R

RAHTITE. A sulphide of copper, iron, and zinc, ($\frac{3}{10}$ Cu, $\frac{1}{10}$ Fe, $\frac{7}{10}$ Zn)S, occurring together with copper pyrites and copper glance, in the copper mines of Ducktown, Tennessee. It is massive, traversed in all directions by shining prismatic cavities, has a lead-grey colour and metallic lustre, hardness = 3.5, sp. gr. = 4.128 (Tyler Shepard, *Sill. Am. J.* [2] xli. 209;—Credner, *Jahresb.* 1867, p. 976).

RAIMONDITE. A hydrated ferric sulphate, $2\text{Fe}^{2+}\cdot 3\text{SO}_4^{2-} + 7\text{H}_2\text{O}$, found in tin mine in Bolivia, in extremely thin tabular hexagonal prisms having an ochre yellow to honey-yellow colour, nacreous lustre, hardness = 4, and sp. gr. 3.190 (3.222 (Breithaupt, *Jahresb.* 1866, p. 952).

RATANHIA-RED. This substance, first obtained by Wittstein as a product of the decomposition of ratanhia-tannic acid, may be prepared, according to Grabowski (*Ann. Ch. Pharm.* cxliii. 274), by precipitating the hot aqueous infusion of rhatan extract with lead acetate, decomposing the precipitate with hydrogen sulphide, and boiling the filtrate with dilute sulphuric acid. The red-brown powder thereby separated, when purified by solution in ammonia and precipitation with hydrochloric acid, and dried at 130° , has the composition $\text{C}^{28}\text{H}^{22}\text{O}^{11}$, which is also that of the substance obtained by Rochleder from the tannin of the horse-chestnut. By fusion with potash, it is resolved, like the latter, into pyrocatechuic acid and phloroglucin, which two bodies are also produced by fusing rhatan extract with potash. The liquid separated from the ratanhia-red contains a difficultly crystallisable sugar.

RESINS (Hlasiwetz a. Barth, *Ann. Ch. Pharm.* cxxxiv. 265; cxxxviii. 61 cxxxix. 83; *Jahresb.* 1865, p. 573; 1866, pp. 626, 631).—The resins of very many plants yield similar products of decomposition by oxidation with potash. A considerable portion of the resin is resolved, as by dry decomposition, into volatile products, aromatic vapours, hydrocarbons, &c., while another portion, of variable amount, separates again in the resinous form; or humus-like products are formed, and in all cases, acetic acid and its nearest homologues. The principal products are: (1) *Protocatechuic acid*, $\text{C}^8\text{H}^6\text{O}^4$, from guaiacum, benzoin, dragon's blood, asafetida, myrrh, acaroid resin, opoponax.—(2) *Paraoxybenzoic acid*, $\text{C}^8\text{H}^6\text{O}^4$, from benzoin, dragon's blood, aloes, acaroid resin.—(3) *Phloroglucin*, $\text{C}^6\text{H}^4\text{O}^3$, from dragon's blood and gamboge.—(4) *Resorcin*, from galbanum, asafetida, gum ammoniacum, sagapenum, acaroid resin, and probably from all resins which yield umbelliferone. *Pyrocatechin* (as also perhaps a small quantity of a body which reddens ferric chloride) probably occurs only as a secondary product resulting from the decomposition of protocatechuic acid. Orcin is formed only from aloes; isuvitic acid and pyrotartaric acid only from gamboge. (See the several Resins.)

Resins are formed artificially by the action of phosphoric anhydride on aldehydes and allied bodies. The resin formed in this manner from bitter almond oil has been already described (p. 327). *Eugene-resin*, formed in like manner from eugenic acid, is an inodorous mass having an aromatically bitter taste and exhibiting violet-blue dichroism in alcoholic solution. In composition it is intermediate between eugenic acid, $\text{C}^{10}\text{H}^{12}\text{O}^2$, and the next more highly oxygenised compound, $\text{C}^{10}\text{H}^{10}\text{O}^4$; by dry distillation it yields an oil which contains creosote, and colours ferric chloride green; with nitric acid it yields scarcely anything besides oxalic acid; with melting potash, considerable quantities of protocatechuic acid, together with a small quantity of acetic acid; its alcoholic solution is precipitated by neutral lead acetate. *Oil of cassia* becomes thickened in contact with phosphoric anhydride. The oils of rue, angelica, and cumin are partially converted into dark brown resins, which when fused with potash, yield only traces of a crystalline substance producing a violet colour with ferric chloride. *Oil of guaiacum* is converted into a thick (phosphoretted) oil, yielding with melting potash a large quantity of protocatechuic acid. *Anise-camphor*, $\text{C}^{10}\text{H}^{12}\text{O}$, gently heated with iodic acid and iodine in alkaline solution, is converted into a brown brittle resin, the portion of which insoluble in alcohol and soluble in ether has nearly the composition of anise-camphor. By fusion with potash it yields a small quantity of a crystalline substance having the properties of anisic acid.

On the formation of resins in the interior of vegetable cells, see Wiesner (*Wien. Akad. Ber.* lii. [2] 118; *Jahresb.* 1865, p. 627).

RESORCIN. $C^6H^4O^2 = C^6H^4(OH)^2$.—This substance, the para-modification (1:4) of oxyphenol, was originally obtained by the action of melting potash on galbanum (iv. 215), and is likewise produced by the same reaction: from para-iodophenol: $C^6H^3IO + KOH = KI + C^6H^4O^2$ (Körner, *Bull. Soc. Chim.* [2] vii. 261);—from paraphenolsulphuric acid: $C^6H^4(OH)(SO^3K) + KHO = K^2SO^3 + C^6H^4(OH)^2$ (Glutz, *ibid.* viii. 361);—from potassium monochlorobenzene-sulphate by fusion with about twice its weight of potassium hydrate (Oppenheim a. Vogt, *Jahresh.* 1868, p. 465);—from umbelliferone: $C^6H^4O^3 + O^2 = C^6H^4O^2 + 3CO^2$ (Hlasiwetz a. Grabowski, *Ann. Ch. Pharm.* cxxxix. 99);—and from asafetida, gum ammoniacum, sagapenum, acaroid resin, and probably from all resins which yield umbelliferone by dry distillation (Hlasiwetz a. Barth, p. 992).

Resorcin crystallises in prisms, which according to Reuss (*Jahresh.* 1866, p. 633) are triclinic, exhibiting the combination $\infty P\infty . \infty P\infty . oP . \infty P . \infty P2 . \infty P2 . P$. According to Rammelsberg's measurements, on the other hand (made on crystals prepared by Oppenheim a. Vogt), they are orthorhombic prisms (p), with bevelled faces (q) resting on the acute lateral edges. Angle $p : p = 118^\circ$ to 119° ; $q : q = 83^\circ$ to 84° ; $p : q = 112^\circ$ to 113° . The edge $\frac{p}{q}$ is apparently perpendicular to $\frac{q}{p}$.

On the power possessed by resorcin of masking the presence of iodine in solution, see IODINE (p. 738).

Resorcin in contact with the vapours of strong nitric acid is gradually converted into a dark red-brown resinous mass, soluble in water, alcohol, and ether, and coloured violet-brown in thin layers by ammonia (Malin).

Resorcin Sulphate, $C^6H^4O^2 \cdot 4H^2SO^4$, crystallises very easily from a solution of 4 pts. warm concentrated sulphuric acid. The very deliquescent strongly acid compound is coloured blood-red by ferric chloride even in very dilute solution, and is easily decomposed by bases. **Quinine-resorcin sulphate**, $C^{20}H^{24}N^2O^2 \cdot C^6H^4O^2 \cdot SO^3 + 1\frac{1}{2}H^2O$, is formed by mixing 2 pts. resorcin with a slightly acidulated solution of 5 pts. quinine sulphate, and crystallises in needles (Malin).

Resorcin-ammonia, $C^6H^4O^2 \cdot NH^3$, is formed by passing dry ammonia gas into a solution of resorcin in anhydrous ether, and separates as an oil, which afterwards crystallises. The colourless crystals, when exposed to the air, deliquesce and turn green, and afterwards blue, in consequence of the formation of a product resembling orcein, and precipitable from the alkaline solution by acids in red-brown flocks (Malin).

Acetyl-resorcin, $C^6H^4(C^2H^3O)^2O^2$, formed by the action of acetyl chloride on resorcin, is an oily liquid, colourless and inodorous after distillation, insoluble in water, and having a burning bitter taste, with sweetish after-taste. **Benzoyl-resorcin**, $C^6H^4(C^7H^5O)^2O^2$, remains, on heating resorcin to 100° with benzoyl chloride, as a red viscid mass, crystallising from hot water in white tale-like scales. The mother-liquor yields laminar crystals of a more soluble compound, probably $C^6H^4(C^7H^5O)^4O^4$. Both compounds are insoluble in water. With **succinyl chloride**, resorcin forms (with evolution of hydrochloric acid), a red-brown uncrystallisable oil, from whose alcoholic solution water throws down a resin, which in alkaline solution exhibits a deep green dichroism. When resorcin is heated with **phosphorus pentachloride**, white uncondensable vapours are evolved, and a semi-carbonised mass remains behind (Malin, *Ann. Ch. Pharm.* cxxxviii. 76).

RETENE. $C^{18}H^{18}$ (v. 97).—This hydrocarbon is produced, together with other polymerides of acetylene, when the vapour of the latter is passed through a red-hot glass tube. The liquid portion of the product subjected to fractional distillation yields several of these polymeric acetylenes, retene passing over at about 360° , and condensing in shining needles (Berthelot, *Jahresh.* 1866, p. 516). It boils at 390° (Berthelot, *ibid.* 1867, p. 39).

Wahlforms (*Zeitschr. f. Chem.* [2] v. 73) has examined retene prepared from a granular buttery mass obtained in the latter part of the distillation of Finland wood-tar. This mass was strongly pressed during a winter temperature; then fused with 10 p. c. benzol, and again pressed; afterwards divided into four fractions by fusion, pulverisation, and partial solution in alcohol; and each of these portions was repeatedly crystallised till its melting point became constant. All the samples finally exhibited a melting point of 98° – 99° , the same as that assigned to retene by Fehling; by Fritzsche and Berthelot, retene is said to melt at 95° . The retene obtained as above yielded a picrate, and a barium salt of disulphoretic acid, agreeing exactly with those described by Fritzsche (v. 97).

Retene exhibits a very characteristic reaction with **chromic acid**. In contact with a mixture of 6 pts. potassium dichromate, 8 pts. sulphuric acid, and $2\frac{1}{2}$ vol. water, it is

Rhamnegin heated to 100° with acetic anhydride is converted into *triacetyl-rhamnegin*, $C^{12}H^{12}(C^2H^3O)^3O^2$, insoluble in water.

The fruits of buckthorn (*Rh. catharticus*) contain two isomeric modifications of rhamnegin, α and β , the latter of which is more soluble in alcohol and more fusible than the former. β Rhamnegin is resolved by dilute acids into a modification of rhamnetin which is soluble in alcohol, crystallises therefrom, and is moreover somewhat soluble in hot water and hot ether, whereas the rhamnetin formed from α rhamnegin is almost insoluble in alcohol. The acetyl-derivatives of the two rhamnetins differ in crystalline form and melting point. The fruits of buckthorn likewise contain a colouring matter insoluble in water, which may be regarded as a glucoside, $C^{12}H^{12}O^{10} = C^{12}H^{10}O^8$ (rhamnetin) + $C^6H^{12}O^6$ (sugar) - H^2O . This is the substance called rhamnin by Lefort, but it differs in composition from rhamnegin. With acetic anhydride this rhamnin yields a hexacetyl derivative (Schützenberger). To these observations Lefort replies (*Compt. rend.* lxvii. 313; *Zeitschr. f. Chem.* [2] v. 669) that the conversion of rhamnegin into rhamnin by molecular transformation takes place only when very dilute acids are employed, whereas the same acids in more concentrated state decompose the rhamnin formed in the first instance into rhamnetin and sugar. Rhamnegin boiled with very dilute acids yields a quantity of rhamnin exactly equal to its own weight; consequently rhamnin and rhamnegin have the same composition.

The constituents of rhamnus berries have also been examined by W. Stein (*Zeitschr. f. Chem.* [2] v. 183, 568). Olive-green berries, freed from fat by means of petroleum ether, were exhausted with boiling water and alcohol, the extracts precipitated by lead acetate, &c. Another portion of the berries was exhausted successively with water, alcohol, and ether. In this manner Stein obtained a yellow colouring matter soluble in water (*rhamnin*), a colouring matter insoluble in water (*rhamnetin*), a substance precipitable by solution of gelatin (*rhamnotannin*), a nitrogenous substance (*rhamnin ferunt*), and a gummy substance (*rhamnin-gum*). Rhamnetin, according to Stein, is identical with quercetin, yielding phloroglucin and quercetic acid when fused with potash. Rhamnin (? Lefort's rhamnegin) in the pure state crystallises from alcohol in microscopic yellow needles. By dilute sulphuric acid, or by the ferment just mentioned, it is resolved into insoluble rhamnetin and rhamnin gum ($C^{12}H^{20}O^8$ or $C^{12}H^{22}O^8$), which reduces cupric oxide when boiled therewith in alkaline solution. The relative quantities of these substances show that rhamnin contains more than 1 mol. rhamnigum to 1 mol. rhamnetin, and therefore that rhamnin has not the same composition as quercitrin.

RHEIC ACID. See RHUBARB.

RHINANTHIN. A glucoside occurring in the seeds of the common yellow rattle (*Rhinanthus Crista Galli*), and giving rise to the violet colour exhibited by bread which is prepared from rye contaminated with these seeds. It is non-azotised, neutral, bitter-sweet, easily soluble in water and alcohol, not precipitated by basic lead acetate. Its alcoholic solution heated with dilute hydrochloric or sulphuric acid becomes bluish-green or greenish-blue. The aqueous solution boiled with dilute sulphuric acid deposits blue-green flocks, and is then found to contain sugar. With nitric acid the solution quickly assumes a deep brown colour (Ludwig, *Zeitschr. f. Chem.* [2] v. 303).

RHODIUM. A method of preparing this metal from precipitated platinum residues is given by Banson (*Ann. Ch. Pharm.* cxlvi. 265; *Zeitschr. f. Chem.* [2] v. 3; *Bull. Soc. Chim.* [2] xi. 308; *Phil. Mag.* [4] xxxvi. 253; *Jahresb.* 1888, p. 280).

RHEADINE. $C^{21}H^{21}NO^5$ (Hesse, *Ann. Ch. Pharm.* cxl. 145; cxlix. 35; *Zeitschr. f. Chem.* [2] ii. 737; v. 252).—An alkaloid existing in all parts of the red poppy (*Papaver Rhæas*), and in the ripe seed-capsules of the white poppy (*P. somniferum*). To obtain it, the aqueous extract of red poppy, strongly concentrated and supersaturated with sodium carbonate, is agitated with ether, and the ethereal solution with acid sodium tartrate. The solution filtered from the ether then yields a greyish-white precipitate which soon becomes crystalline, and when treated with water and boiling alcohol, whereby a small quantity of thobaine or an allied base is removed, is dissolved in acetic acid, decolorised with animal charcoal, and reprecipitated by ammonia. Larger crystals are obtained by adding the acetic acid solution to hot alcohol containing ammonia.

Rheadine forms small white prisms nearly insoluble in ether, alcohol, benzol, chloroform, water, ammonia, sodium carbonate, and lime-water; it requires for solution 1100 pts. alcohol of 80 p. c., and 1280 pts. ether at 18°. The base, both in the free state and dissolved in acids, is tasteless and not poisonous. It melts at

232°, a portion subliming in small white prisms, especially in a stream of gas. Its solutions in weak acids, not in excess, are colourless; those in somewhat stronger acids, especially in hydrochloric and sulphuric acids, have a purple-red colour. This coloration, which disappears on addition of alkalis, and is restored by acids, is so intense that 1 pt. of the base will colour 10,000 pts. of water purple-red, 200,000 pts. deep rose-red, and 800,000 pts. still distinctly red, although only 5 p. c. of the base is converted into the colouring substance. The colourless solution of rheadine in acids is precipitated by tannic acid, and by mercuric, auric, and platonic chloride. The platinum salt has the composition $2(C^{21}H^{21}NO^4 \cdot HCl) \cdot PtCl^4 + 2H^2O$. The hydriodide, $C^{21}H^{21}NO^4 \cdot HI + 2H^2O$, separates on adding potassium iodide to a solution of the acetate, as a dense crystalline mass, consisting of small microscopic prisms, which give off half their water over sulphuric acid, the rest at 120°. The aqueous solution becomes red by prolonged boiling, part of the rheadine being converted into rheagenine; and on adding a drop of hydrochloric or sulphuric acid, the whole of the base is decomposed, the solution acquiring a purple-red colour. Cold dilute sulphuric acid converts rheadine into a colourless resinous mass, which soon dissolves with splendid purple colour; on boiling the solution, it becomes dark purple, and on cooling deposits small prisms, brown-red by transmitted, green by reflected light, the liquid retaining rheagenine amounting to 99 p. c. of the rheadine, together with the colouring matter.

Opium contains a base different from rheadine, but giving the same colour-reactions with sulphuric acid.

RHEAGENINE. A base isomeric with rheadine, and formed from it by the action of dilute mineral acids; it does not occur ready-formed in the poppy. When precipitated by ammonia from the solution, decolorised by animal charcoal, and recrystallised from alcohol, it forms small white prisms or laminae, slightly soluble in ether, alcohol, water, and ammonia, easily and without colour in acids. The alcoholic solution blues reddened litmus. The base melts at 223°, but is not sublimable. The salts have a bitter taste, and some of them crystallise well. The sulphate is very soluble in water, and dries up to a varnish; its solution is precipitated by potassium dichromate, potassio-mercuric iodide, mercuric chloride, and acid platonic chloride. The hydrochloride forms concentrically grouped needles, easily soluble in water and in alcohol, precipitated from the aqueous solution by common salt. The platinochloride contains $2(C^{21}H^{21}NO^4 \cdot HCl) \cdot PtCl^4$. The hydriodide, $C^{21}H^{21}NO^4 \cdot HI$, forms short heavy prisms, moderately soluble in boiling, sparingly in cold water, nearly insoluble in aqueous potassium iodide. The nitrate forms vitreous prisms, slightly soluble in cold water, melting and partly dissolving in boiling water. The oxalate crystallises in thin prisms.

RHUBARB. The portion of the aqueous extract of rhubarb-root which is soluble in alcohol contains, according to Kubly (*Chem. Centr.* 1867, p. 1056), the following constituents: 1. *Rheotannic acid*, $C^{26}H^{26}O^{14}$, precipitated (together with phæoretin) by lead acetate, and extracted by water after decomposition of the precipitate by hydrogen sulphide. It is a yellow-brown powder, insoluble in ether, but soluble in alcohol and in water; the brown, acid, aqueous solution precipitates organic bases white, ferric salts black-green, lead acetate and ferrous salts whitish-grey, but forms no precipitate with tartar-emetic. The lead precipitate contains $C^{26}H^{26}O^{14} \cdot 2PbO$. By boiling with acids or alkalis, rheotannic acid is resolved into fermentable sugar and red-brown amorphous *rheic acid*, $C^{26}H^{16}O^9$, which behaves with reagents like rheotannic acid.—2. *Phæoretin*, $C^{34}H^{16}O^7$, extracted by hot alcohol from the lead sulphide obtained in the preparation of rheotannic acid; it has essentially the properties described by Schlossberger a. Döpping (iv. 387). When the liquid filtered from the lead salt of rheotannic acid is freed from excess of lead by hydrogen sulphide, the resulting lead sulphide yields to water a large quantity of sugar, and to alcohol the following substances: 3. An indifferent substance, $C^8H^8O^2$, crystallising in prisms, insoluble in ether, slightly soluble in hot alcohol and water, and precipitated by lead acetate.—4. An orange-coloured bitter substance, designated by Kubly as *chrysophane*, which is insoluble in ether, but soluble in water and in alcohol, and decomposed by acids, with formation of sugar and flocculent chrysophanic acid.

RHUS. According to Maisch (*Chem. News*, xiii. 112), the poisonous principle of *Rhus Toxicodendron* is not a volatile base, as stated by Khittel (v. 109), but a volatile acid (*toxicodendronic acid*), which differs from formic acid by the circumstance that its sparingly soluble mercurous salt is not reduced by boiling. In the state of vapour or in aqueous solution it produces blisters and eruptions on the skin.

RHYOLITE. A rock occurring in trachytic and basaltic formations. For analyses, see *Jahresb.* 1865, p. 916; 1866, pp. 969, 976.

RICHMONDITE. This name is proposed by Kenngott (*Jahrb. Min.* 1866, p. 829) for the aluminium phosphate hitherto designated as *Gibbsite* (ii. 838).

RICINELAÏDIC ACID. $C^{18}H^{34}O^3$ (Ulrich, *Bull. Soc. Chim.* [2] ix. 225; *Jahresb.* 1867, p. 408).—This acid may be prepared by heating ricinoleic acid with pure nitric acid till red vapours are evolved, quickly cooling the product in cold water, pressing the solidified acid, and recrystallising it from hot alcohol. It crystallises in tufts of soft needles melting at 50° . It unites directly with bromine, forming oily *Ricinelaïdic dibromide*, $C^{18}H^{32}O^3Br^2$, which is converted by potash-ley even at ordinary temperatures into *Monobromoricinelaïdic acid*, $C^{18}H^{32}BrO^3$. This latter acid heated with alcoholic potash forms, together with potassium bromide, a solid acid different from ricinostearolic acid, melting at 71° , and crystallising from alcohol in short needles.

RICINOLEIC ACID. $C^{18}H^{34}O^3$ (Ulrich, *loc. cit.*).—By treating this acid at ordinary temperatures with 2 mol. phosphorus pentachloride, there is formed, according to the equation,

a heavy oil, which is slowly decomposed by water, yielding a mobile, pungent liquid, floating on water, and having the composition $C^{18}H^{32}ClO^2$. This oil treated with alcoholic potash, but not with sodium-amalgam, yields a viscid oil, nearly free from chlorine, and exhibiting the characters of ricinoleic acid.

Ricinoleic dibromide, $C^{18}H^{32}O^3Br^2$, produced by gradually mixing cooled ricinoleic acid with 1 mol. bromine, and purified by saponification with weak potash-ley, is a heavy oil, colourless at first, but afterwards turning brown, insoluble in water, easily soluble in alcohol and ether. The potassium and ammonium salts are slightly soluble in water, easily in alcohol; the other salts are viscid glutinous masses.

Monobromoricinoleic acid, $C^{18}H^{32}BrO^3$, is formed by treating the dibromide with an alcoholic solution of 2 mol. potassium hydrate, and separates, on addition of hydrochloric acid, as a clear yellowish oil, not decomposing at 100° , easily soluble in alcohol and ether, forming with potash and ammonia, soaps slightly soluble in water. Mixed in a cooled vessel with 1 mol. bromine, it forms a yellowish, viscid, easily decomposable oil—probably *monobromoricinoleic dibromide*—which is quickly reconverted by alcoholic potash into monobromoricinoleic acid.

RICINOSTEAROLIC ACID. $C^{18}H^{32}O^3$, produced by heating monobromoricinoleic acid to 80° for about 8 hours with 2 mol. bromine, and purified by recrystallisation from alcohol, forms tufts or nodular groups of colourless needles, easily soluble in alcohol and ether, volatilising without decomposition, easily saponified by alkalis. The ammonium salt crystallises in slender needles, easily soluble in water, and gradually giving off all its ammonia on boiling; the potassium salt, which is likewise easily soluble, crystallises in slender needles or as a laminar mass; the barium salt, $(C^{18}H^{31}O^3)^2Ba$, is a precipitate insoluble in ether, crystallising from alcohol in laminae which melt at 135° ; the silver salt, $C^{18}H^{31}O^3Ag$, is a granular precipitate gradually decomposed by hot alcohol (Ulrich, *loc. cit.*).

Ricinostearolic dibromide, $C^{18}H^{30}O^3Br^2$, is formed as a thickish, yellowish oil, on gradually mixing cooled ricinostearolic acid with 1 mol. bromine. In contact with excess of bromine, it is converted into the *tetrabromide* $C^{18}H^{28}O^3Br^4$, a heavy, easily decomposable oil. The dibromide is decomposed by alcoholic potash at 150° (the tetrabromide at ordinary temperatures), yielding ricinostearolic acid smelling of octyl alcohol.

RICINOSTEAROXYLIC ACID. $C^{18}H^{32}O^4$, is obtained by prolonged heating of ricinostearolic acid with $1\frac{1}{2}$ pt. recently precipitated silver oxide, decomposing the resulting silver salt with hydrochloric acid, and recrystallising the acid extracted by ether. It crystallises from alcohol in dendritic groups of needles, melts at 78° , solidifies to a hard alabaster-like mass, and is easily saponified by alkalis. The ammonium salt crystallises in ring-shaped groups of needles soluble in alcohol; the silver salt, $C^{18}H^{31}O^4Ag$, is a granular precipitate decomposed by hot alcohol; the barium salt, $(C^{18}H^{31}O^4)^2Ba$, separates from alcoholic solution as a jelly. Ricinostearoxylic acid is distinguished from the isomeric compound, stearoxylic acid, by not uniting with bromine without evolution of gas. When ricinoleic dibromide is heated to 100° with silver oxide and water, there is formed, together with octylic alcohol, a mass which, when decomposed by hydrochloric acid, yields to ether a yellow rancid-smelling oil, which deposits ricinostearoxylic acid melting at 78° (Ulrich, *loc. cit.*).

ROCHELLA. See ORCHELLA-WEEDS.

ROSANILINE. The salts of this base heated to 18° with potash in alcoholic solution yield a yellowish liquid from which water throws down free rosaniline, coloured deep yellow by admixture of chrysaniline, as is also the wash-water; on exposure to air and light, the precipitate turns orange-red, and the wash-water in sunshine turns blue. *Rosatoluidine salts* similarly treated also yield a yellowish liquid, from which water throws down the base in faintly reddish flocks, both the precipitate and the wash-water becoming violet when exposed to sunshine. *Rosatoluidine salts* heated to 280° for several days with glycerin and a little alcohol form a red liquid which is precipitated by ammonia, but not by water; the precipitate is dark violet, the wash-water light violet. *Rosaniline salts* similarly treated yield a red-brown precipitate and a yellow-brown wash-water. *Rosaniline salts* are less soluble than *rosatoluidine salts*, and the free base is more easily separated from the former than from the latter by alkalis. The solutions of rosaniline salts used in dyeing exhibit a faint yellowish reflex; those of *rosatoluidine* do not. The colouring power of rosaniline salts is to that of *rosatoluidine salts* as 100° to 140° (A. Roussille, *Bull. Soc. Chim.* [2] vi. 354).

On the reaction of the *camphene hydrochlorides*, $C^{10}H^{16} \cdot HCl$ and $C^{10}H^{16} \cdot 2HCl$, with rosaniline, see **TEREBENES**.

Action of Aldehydes on Rosaniline.—When the yellow solution of rosaniline sulphite (or other salt) in aqueous sulphurous acid is mixed with a few drops of an aldehyde (bitter almond oil, *œnanthol*, or *valeral*), the rosaniline being kept in excess, sulphurous anhydride is given off, the solution turns red and afterwards violet, and gradually deposits copper-coloured crystalline scales consisting of the mono-acid salts of the following bases:

These bases do not form triacid salts. The copper-coloured *arsenate of heptylidene-rosaniline* consists of $C^{20}H^{16}N^3 \cdot AsHO^3$; the yellow *platinchloride* is $C^{20}H^{16}N^3 \cdot 2HCl \cdot PtCl^4$. By acting upon these bases in alcoholic solution with ethyl iodide (or with iodine and phosphorus) the typic hydrogen-atom may be replaced by ethyl. The salts of the ethylated bases are insoluble in ether, water, and dilute acids, but dissolve easily in alcohol, forming violet solutions (Schiff, *Bull. Soc. Chim.* [2] vii. 518).

œnanthol forms with crystallised rosaniline acetate, even at ordinary temperatures, a compound which dissolves in alcohol with blue colour, and yields with caustic potash red crystalline flocks of *triheptylidene-dirosaniline*, $C^{61}H^{48}N^6$:

This base, as well as its salts, decomposes below 100°, especially in presence of excess of *œnanthol*, forming a yellow resinous mass composed for the most part of *heptylidene-ditoluidene-diamine*, $(C^7H^{14})(C^7H^6)^2N^2$. The decomposition in presence of *œnanthol* may perhaps be represented by the following equation:

The formation of heptylidene-diphenylene-diamine has not however been distinctly proved; it has merely been observed that the heptylidene-ditoluidene-diamine is accompanied by another base of lower boiling point. *Benzoic aldehyde* forms with rosaniline at 90°–100° a violet mass, which, from the analysis of its platinum salt, appears to contain *toluidene-rosaniline*, $[(C^{20}H^{16})(C^7H^6)H]N^3$; at 120° a crystalline copper-red product is formed; and at 150°–160°, with excess of benzoic aldehyde, there is obtained a heavy yellow oil from which alcohol separates a sandy powder (Schiff, *Bull. Soc. Chim.* [2] v. 291).

Hydrocyan-rosaniline. $C^{20}H^{16}N^3 \cdot HCN$ (v. 115).

ROSE OIL. The camphor or steareptene of this oil (obtained from roses grown at Mitcham), when carefully fused by the heat of the sun, solidifies on cooling, in

microscopic, truncated, six-sided pyramids, not belonging to the rhombohedral system. It has the composition of an olefine, C^8H^{12} , melts at 32.5° , gives off vapours at 150° , begins to boil at 272° , boils completely at 275° , turns brown and black at 300° . When oxidised by fuming nitric acid, it yields succinic acid, together with a small quantity of oxalic acid, and perhaps valeric and formic acids. A mixture of potassium chromate and sulphuric acid produces no perceptible effect upon it, beyond the omission of a faint odour of acrolein (Flückiger, *Zeitschr. f. Chem.* [2] vi. 126).

ROSOCYANIN. See CURCUMIN.

ROSOLIC ACID. $C^{20}H^{16}O^3$ or $C^{20}H^{18}O^4$.—The formation of this acid from rosaniline by the action of nitrous acid has already been noticed (v. 584). The equations representing it are as follows:

Rosaniline.

Azorosaniline.

Azorosaniline.

Rosolic acid.

The deep red solution of rosaniline turns brown when mixed with excess of hydrochloric acid, then yellow when nitrous acid is passed into it, and deposits on boiling a dark-coloured solid body which differs from rosolic acid obtained from phenol (by the action of sulphuric acid on a mixture of phenol and oxalic acid) in this respect, that its salts are not coloured darker by potassium ferricyanide. It seems probable that the rosolic acid obtained from phenol may contain a body (likewise produced from leucaniline, and therefore called *leucorosolic acid*) which induces the darker coloration by the ferricyanide. The same body is formed by the reducing action of zinc and hydrochloric acid on rosolic acid obtained from rosaniline; and, on the other hand, rosolic acid from phenol, after treatment with potassium ferricyanide, precipitation with acid, and solution in alkali, exhibits exactly the same characters as that which is produced from rosaniline (Wanklyn & Caro, *Proc. Roy. Soc.* xv. 210).

Caro (*Phil. Mag.* [4] xxxii. 126) has also endeavoured to determine whether the formation of rosolic acid from phenol requires the presence of a substance which, like cresol, oxalic acid, &c., contains carbon in the form in which it exists in the fatty series. He finds that (similarly to the formation of rosaniline) pure phenol or pure cresol treated with manganese dioxide, mercuric sulphate, arsenic anhydride, or iodine, does not yield a trace of rosolic acid. This acid is however always formed when a mixture of phenol and cresol is employed; also from pure phenol (but not from cresol) heated with strong sulphuric acid and oxalic acid, with sulphuric acid and amyl iodide, with bromoacetic acid, with acetic acid and iodine, with formates and iodine, and in considerable quantity with iodoform. In a similar manner rosaniline is produced from pure aniline (free from toluidine) by heating with iodoform or with lead formate and iodine, and in smaller quantity by the action of chloroform, carbon chloride, or cyanogen iodide. With toluidine there is formed under the same circumstances a brown product not containing rosaniline. Hence Caro concludes that in rosolic acid, as in rosaniline, part of the carbon is combined in the same manner as in the aromatic bodies, part as in the fatty bodies, as indicated by the following equations of formation:

RUFIGALLIC ACID. The crystalline grains of this acid obtained by treating dry gallic acid with strong sulphuric acid (v. 133) are anhydrous, and have the composition $C^7H^4O^4$; they have the colour of carmine, and appear under the microscope as acute rhombohedrons. The amorphous acid $C^7H^4O^4 \cdot H^2O$ * gives off its water (10.58 p. c.) at 135° . The acid may be sublimed in cinnabar-red prismatic crystals, which do not lose weight at 125° . It is insoluble in cold, slightly soluble in boiling water, also in alcohol and ether; in potash and ammonia it dissolves with red colour when the air is excluded, with brown colour in contact with air; the alcoholic solution is neutral. It does not yield pyrogalllic acid when heated with potash or lime. Baryta-water does not dissolve it, but converts it into an indigo-blue mass soluble in

* Misprinted $C^7H^4O^4$ in vol. v. p. 13.

potash (Wagner, *Chem. Centr.* 1861, p. 47). By fusion with potash it is converted into oxyquinone, $C^{10}H^4O^2$ (Malin, p. 893).

According to Löwe (*J. pr. Chem.* cvii. 296; *Zeitschr. f. Chem.* [2] vi. 128), the formula of rufgallie acid is $C^{10}H^4O^3$, and its formation from gallic acid is attended with the formation of a product of oxidation, the oxygen being supplied at the expense of the sulphuric acid: other dehydrating agents, zinc chloride for example, do not convert gallic into rufgallie acid. By strong potash solution, and especially by alcoholic potash, it is converted into a blue-black salt.

RUTIN. According to Spiess a. Sostmann (*Jahresb.* 1865, p. 587), this substance, $C^{23}H^{12}O^{17}$ (or $C^{23}H^{10}O^{15} \cdot 2H^2O$), is easily obtained from commercial Chinese yellow berries in grains (the undeveloped flower-buds of *Sophora japonica*, known as Waifu), whereas Chinese yellow berries in pods (the fruit of *Gardenia radicans* and *G. florida*) contain, not rutin, but mannite.

S

SACCHARIC ETHER. Crystallised ethyl saccharate gently heated with 4 mol. acetyl chloride, is converted into a crystalline compound, $C^{10}H^{10}O^8$, mixed with an oil insoluble in water. The crystalline body is perhaps formed in the manner shown by the equation:

When the crystalline compound of ethyl saccharate and calcium chloride is heated to 100° with somewhat more than an equal weight of acetyl chloride, a gummy mass is formed which gives up to anhydrous ether an oil easily soluble in water and alcohol, and solidifying for the most part in the crystalline form over sulphuric acid. The crystals consist of *ethylic tetraacetyl-saccharate*, $C^6H^4(C^2H^3O)^4O^8 \cdot (C^2H^3)^2$. This ether crystallises from alcohol in monoclinic prisms, melting at 61° , insoluble in water, soluble in alcohol and ether, and resinised by alcoholic potash (Baltzer, *Dudl. Soc. Chim.* [2] x. 263).

SAFFRON (B. Weiss, *J. pr. Chem.* ci. 65).—When dried saffron, after exhaustion with ether, which removes a small quantity of a yellowish oil, is digested with water, gum, vegetable mucilage, inorganic salts, and sugar are dissolved, together with the unaltered colouring matter of the saffron; from this solution, the gum, mucilage, and inorganic salts may be precipitated by absolute alcohol; and the filtrate mixed with ether deposits the colouring matter mixed with small quantities of sugar and salts. This colouring matter, polychroite, $C^{18}H^{20}O^{18}$ (?), forms an orange-yellow precipitate which dries up over sulphuric acid to a friable, ruby-coloured, deliquescent mass. It is inodorous, has a faint, sweetish taste, dissolves easily in water and in dilute alcohol, but is nearly insoluble in absolute alcohol. The aqueous solution is turned brown by hydrogen sulphide, and is decolorised by nitrous acid or chlorine. By dilute acids it is resolved into a red secondary colouring matter (crocin), sugar, and an aromatic oil having the characteristic odour of saffron. On heating its aqueous solution with dilute sulphuric acid (not in excess) in a retort through which a stream of hydrogen is passed, crocin separates as a red powder, while the oil distils over.

Crocin has the composition $C^{18}H^{18}O^8$; an orange-yellow lead salt precipitated from its alcoholic solution by lead acetate contains $(C^{18}H^{17}O^8)^2Pb$; a red substance very much like crocin, left undissolved by ether in the preparation of polychroite, consists of $2C^{18}H^{18}O^8 \cdot 3H^2O$. Crocin dissolves very sparingly in water, easily in alcohol and in dilute alkalis. From the alcoholic solution it is precipitated by ether, from solution in alkalis by acids, in purple-red flocks. Heated with strong potash-ley, it decomposes, with evolution of pungent vapours. With strong sulphuric acid it acquires a deep blue colour, gradually changing to violet and brown; nitric acid colours it green, changing to yellow-brown. Crocin suspended in water dissolves in nitric acid to a colourless liquid, without formation of oxalic acid; it is decolorised by chlorine; not affected by sulphurous acid.

The mobile *volatile oil* obtained in the decomposition of polychroïte is yellow, has the odour of saffron, and boils at 208°–210°. It mixes in all proportions with alcohol and ether, is insoluble in water, but is decomposed by prolonged contact with it, the liquid acquiring an acid reaction and becoming covered with white films. Heated with potash-ley it decomposes, giving off pungent vapours; alcoholic potash converts it into a resin. It quickly reduces silver solution, especially on addition of ammonia; is coloured brown by solution of iodine in potassium iodide; does not unite with alkaline bisulphites.

The decomposition of polychroïte by acids appears to take place in the manner represented by the equation:

SAFRENE and SAFROL. See SASSAFRAS OIL.

SALAMANDRINE. $\text{C}^{24}\text{H}^{60}\text{N}^2\text{O}^3$.—An alkaloïd obtained from the poisonous secretion of the cutaneous glands of the land salamander (*Salamandra maculata*). It is not volatile, crystallises with water, dissolves easily in water and in alcohol, and has an alkaline reaction. The *hydrochloride*, $\text{C}^{24}\text{H}^{60}\text{N}^2\text{O}^3 \cdot 2\text{HCl}$, crystallises in needles, but becomes amorphous in drying (Zalesky, *Bull. Soc. Chim.* [2] vi. 344; *Jahresb.* 1866, p. 755).

SALEP. The orchis-roots known by this name contain, according to Dragendorff (*Jahresb.* 1865, p. 633), 48·1 p. c. dextrin, arabin, and semi-soluble vegetable mucilage, 27·3 starch, 1·2 sugar, 2·4 cellulose, 4·9 proteids, and 4·8 p. c. ash (containing 28·8 p. c. phosphoric anhydride, and 23 p. c. potash).

SALYDRANILIDE.

SALYDRETHANILIDE.

} See SALICYLOI, AMIDES OF (p. 1011).

SALICIN. $\text{C}^{13}\text{H}^{11}\text{O}^7$. This compound is not decomposed by water in closed vessels, either at ordinary temperatures or at 100°; but in contact with the air the aqueous solution is soon found to contain sugar and saligenin, at the same time that mould forms on its surface. If this mould be introduced into a salicin-solution kept from contact with the air, the resolution of the salicin into sugar and saligenin takes place more quickly (Moitessier, *Jahresb.* 1866, p. 676).

Salicin dissolves in a solution of sodium in alcohol, the liquid after a while solidifying to a crystalline pulp, which when washed with alcohol and dried at a gentle heat yields a white brittle mass of *sodium-salicin*, $\text{C}^{13}\text{H}^{11}\text{NaO}^7$ (Perkin, *Chem. News*, xviii. 110).

Bromosalicin, $\text{C}^{13}\text{H}^{11}\text{BrO}^7$, is formed by gradually adding bromine to a solution of salicin in 20 pts. water. The liquid then solidifies to a pulp, which, when freed by ether from a resinous substance, crystallises from water in four-sided prisms of hydrated bromosalicin, $\text{C}^{13}\text{H}^{11}\text{BrO}^7 \cdot 2\text{H}^2\text{O}$. This compound tastes bitter, like salicin, is easily soluble in water and alcohol, insoluble in ether, gives off its water at 110°, melts at 160°, and decomposes at about 200°. Bromosalicin is decomposed by emulsin, less easily than salicin; the bromosaligenin thereby produced forms a blue colour with ferric chloride, like saligenin. Acids added to its solution throw down bromosaliretin. Its aqueous solution is precipitated by basic lead acetate. Bromosalicin treated in warm solution with excess of bromine, is converted into a pulverulent compound containing 25·28 p. c. bromine (O. Schmidt, *Zeitschr. f. Chem.* [2] i. 320).

Derivatives of Salicin containing Acid Organic Radicles.—Salicin treated at ordinary temperatures with acetyl chloride is converted into a compound of acetyl chloride with tetracetyl-salicin:

This compound is insoluble in water, slightly soluble in ether, easily soluble in alcohol, from which it is deposited in small crystals. By hot dilute mineral acids it is resolved into sugar, saliretin, acetic acid, and hydrochloric acid; by alkalis into salicin and the same acids; with silver nitrate it yields tetracetyl-salicin, acetic acid, and silver chloride. *Tetracetyl-salicin* is soluble in water, alcohol, and ether, crystallises in needles, and reacts with acids and alkalis in the manner just mentioned: it is not decomposed by emulsin. The chlorides of butyryl, valeryl, and caproyl yield with salicin uncrystallisable products, and the lead-compound of salicin heated to 100° with ethyl iodide yields only a resinous body. Monochlorosalicin is converted by acetyl chloride into *acetochlorosalicin*, $\text{C}^{13}\text{H}^{11}\text{Cl}(\text{C}^2\text{H}^3\text{O})^4\text{O}^7$, which crystallises from alcohol, and reacts like tetracetyl-salicin (Moitessier, *loc. cit.*).

According to Schiff (*Zeitschr. f. Chem.* [2] v. 51), tetracetyl-salicin may be obtained directly by treating salicin with a large excess of acetyl chloride at a rather low

as the quantity of acid present is greater. Paraoxybenzoic acid undergoes the same decomposition alone or with water at 200° – 210° , and with the above-mentioned acids at 135° – 140° ; but the decomposition of oxybenzoic acid requires a much higher temperature (Graebe, *Ann. Ch. Pharm.* cxxxix. 134).

Oxidation.—Salicylic acid heated with potassium dichromate and sulphuric acid gives off 150 to 168 pts. CO_2 for every 100 pts. $\text{C}_7\text{H}_5\text{O}_3$; these numbers show that the phenyl residue of the salicylic acid is oxidised under these circumstances; 5 mol. CO_2 would amount to 159 pts.. 7 mol. to 223.2 pts. Formic acid is likewise produced (Schröder a. Prinzhorn, *Ann. Ch. Pharm.* cl. 9).

Bromosalicylic Acid. $\text{C}_7\text{H}_3\text{BrO}_3$.—This compound, which Cahours obtained by triturating salicylic acid with bromine (v. 156), is also produced by gently heating salicylic acid with phosphorus pentabromide. On treating the product with water, an oily liquid separates which quickly solidifies; and on dissolving this mass in ether or alcohol, and evaporating, crystals of bromosalicylic acid separate, together with a thick pitchy mass of bromosalicylic anhydride which quickly solidifies. The anhydride crystallises from boiling water in small white needles, melts at 164° – 165° , sublimes at 150° – 155° , and is converted into bromosalicylic acid by boiling with caustic alkalis. Methyl salicylate is converted by phosphorus pentabromide into *methyl bromosalicylate*, $\text{C}_7\text{H}_3\text{Br}(\text{OH})\text{COOCH}_3$, which crystallises from alcohol in needles, melts at 36° – 38° , and boils without decomposition at 265° – 266° (L. Henry, *Zeitschr. f. Chem.* [2] v. 479).

Iodosalicylic Acids. Liechti (*Ann. Ch. Pharm. Suppl.* vii. 129; *Zeitschr. f. Chem.* [2] vi. 193) prepares mono- and di-iodosalicylic acid by agitating a hot solution of 1 pt. salicylic acid in about 25 pts. water with a mixture of 1 pt. iodine and $\frac{1}{4}$ pt. iodic acid, keeping the liquid hot for some time and decanting from the oil which falls to the bottom. This oil, which solidifies on cooling, is a mixture of the two iodosalicylic acids, which may be separated by converting them into sodium salts by Lautemann's method (v. 157), picking out the crystals of the two salts, and purifying them by several recrystallisations. If a smaller proportion of water is used, the product consists chiefly of di-iodosalicylic acid.

Mono-iodosalicylic acid, $\text{C}_7\text{H}_4\text{IO}_3$, melts under water at 98° , in the dry state at 184° (196° according to Lautemann); dissolves in 893 pts. water at 20° , in 104 pts. at the boiling heat, and decomposes when its solution is boiled for some time. **Sodium mono-iodosalicylate**, $\text{C}_7\text{H}_3\text{IO}_3\text{Na}$, dissolves in 13 pts. water at 20° , sparingly in cold, more easily in warm alcohol of ordinary strength, in traces only in ether. The **potassium salt**, $\text{C}_7\text{H}_3\text{IO}_3\text{K} + 3\text{H}_2\text{O}$, forms colourless laminae; gives off its water at 100° ; dissolves in 5.2 pts. water at 20° , also in cold alcohol, less easily in ether. Its aqueous solution, as well as that of the sodium salt, turns brown on exposure to the air. The **ammonium salt**, $2\text{C}_7\text{H}_3\text{IO}_3(\text{NH}_4) + 7\text{H}_2\text{O}$, crystallises in groups of thick needles; dissolves in 10.5 pts. water at 20° , and is about as soluble as the sodium salt in alcohol and ether; gives off its water at 100° without losing its neutral reaction. The acid is decomposed by prolonged heating with ammonia to 160° in sealed tubes. The **barium salt**, $(\text{C}_7\text{H}_3\text{IO}_3)_2\text{Ba} + 4\text{H}_2\text{O}$, crystallises in neutral highly lustrous scales, soluble in 78 pts. water at 20° , sparingly in alcohol, nearly insoluble in ether; gives off 3 mol. water over sulphuric acid, the fourth at 100° . A **basic barium salt**, $\text{C}_7\text{H}_3\text{IO}_3\text{Ba} + 2\text{H}_2\text{O}$, separates in tufts or stars of small needles when a hot-saturated solution of the neutral salt is poured into baryta-water, saturated in the cold, and then warmed; it dissolves in small quantity only in boiling water, but the solution is strongly alkaline; after drying over sulphuric acid, it gives off about $\frac{2}{3}$ of its crystallisation-water at 100° , the rest at 150° .

Di-iodosalicylic acid, $\text{C}_7\text{H}_2\text{I}_2\text{O}_3$, precipitated from its sodium salt by hydrochloric acid, forms an indistinctly crystalline powder, and when recrystallised from hot water, a white felted mass, which dissolves in 1428 pts. water at 15° , in 656 pts. of boiling water, easily in alcohol and ether; at 193° it becomes soft and brown, but does not melt; at 197° it gives off violet vapours, and becomes continually darker in colour. The **sodium salt**, $2\text{C}_7\text{H}_2\text{I}_2\text{O}_3\text{Na} + 5\text{H}_2\text{O}$, forms long, highly lustrous, flat needles mostly grouped in druses; neutral, soluble in 49.6 pts. water at 20° , moderately soluble in alcohol, nearly insoluble in ether; becoming anhydrous at 120° . The **potassium salt**, $\text{C}_7\text{H}_2\text{I}_2\text{O}_3\text{K} + \text{H}_2\text{O}$, forms short, thick, microscopic prisms having a strong reddish tinge, soluble in 180.7 pts. water at 20° , easily in alcohol, sparingly in ether; becomes anhydrous at 100° . The **ammonium salt**, $2\text{C}_7\text{H}_2\text{I}_2\text{O}_3(\text{NH}_4) + \text{H}_2\text{O}$, forms arborescent groups of small needles, neutral, soluble in 316 pts. water at 20° , moderately soluble in alcohol, nearly insoluble in ether; becomes anhydrous at 100° . The **neutral barium salt**, $(\text{C}_7\text{H}_2\text{I}_2\text{O}_3)_2\text{Ba} + 3\text{H}_2\text{O}$, forms shining needles, neutral, soluble in 1350 pts. water at 18° , very slightly soluble in alcohol, still less in ether.

gives off 1 mol. water at 100°, the rest at 150°. A *basic barium salt*, $2C^7H^2I^2O^3Ba + 3H^2O$, is obtained, like the corresponding mono-iodosalicylate, in small silky tablets, dissolving very sparingly, but with strong reaction, in water, becoming anhydrous at 150°. The *calcium salt*, $(C^7H^2I^2O^3)^2Ca + 5H^2O$, separates from a boiling aqueous solution on cooling in highly lustrous neutral needles, soluble in 1160 pts. water at 18°, becoming anhydrous at 120° (Liechti).

Amidosalicylic or Meta-amidoxybenzoic acid, $C^7H^7NO^3 = C^6H^2(NH^2)\left\{\begin{smallmatrix} OH \\ CO^2H \end{smallmatrix}\right.$, is produced by the action of tin and hydrochloric acid on nitrosalicylic acid (Beilstein, *Ann. Ch. Pharm.* cxxx. 242):

also by heating the nitro-acid with fuming hydriodic acid and a little phosphorus to 120°–130°, and by treating the nitric acid with sodium-amalgam (Moitessier, *Jahresb.* 1865, 385); not by the action of ammonium sulphide (R. Schmitt, *Zeitschr. Ch. Pharm.* 1864, 321).

The liquid obtained by the first process solidifies to a crystalline pulp, consisting of a compound of stannous chloride with the hydrochloride of amidosalicylic acid, which, when dissolved in water, decomposed with hydrogen sulphide, and evaporated in a stream of that gas, yields colourless crystals of the hydrochloride; and this, when carefully neutralised in aqueous solution with caustic soda, yields a network of satiny crystals of amidosalicylic acid. This acid is insoluble in cold water and in alcohol, sparingly soluble in hot water. Its hot aqueous solution exposed to the air quickly deposits a brown amorphous decomposition-product, which is likewise formed by the action of acids or alkalis. Ferric chloride first colours the solution deep cherry-red, and then forms a black-brown precipitate (more quickly on addition of chlorine or bromine).

The salts of amidosalicylic acid are permanent in the dry state, but very unstable in solution; those of the alkali-metals and alkaline-earth metals are easily soluble, crystallisable, and mostly black-brown; those of the heavy metals are sparingly soluble, easily decomposable precipitates (Schmitt).

Hydrochloride of Amidosalicylic acid, $C^7H^2NO^3.HCl$, crystallises in long needles easily soluble in water and alcohol at the boiling heat. The solution, which decomposes even on exposure to air, deposits brown flocks on addition of auric or platine chloride. The *hydriodide*, $C^7H^2NO^3.HI$, crystallises in yellowish needles or laminae more stable in solution than the hydrochloride. The *sulphate*, $2C^7H^2NO^3.SO^2H^2 + H^2O$, crystallises in slightly soluble colourless prisms (Schmitt).

Diamidosalicylic acid, $C^7H^4N^2O^3 = C^7H^4(NH^2)^2O^3$, is produced by the action of phosphorus iodide and water on methyl dinitrosalicylate (v. 164):

The resulting liquid, decolorised by phosphorus at the boiling heat and filtered from amorphous phosphorus, deposits on evaporation a crystalline mass of the hydriodide of diamidosalicylic acid; and on decomposing this compound in alcoholic solution with sodium carbonate not in excess, diamidosalicylic acid separates in colourless stellate groups of needles. It is insoluble in alcohol, but dissolves easily in hot water and in dilute acids, excepting acetic acid. The solutions quickly decompose in contact with the air, so that the acid becomes coloured even by recrystallisation from water. The aqueous solution is coloured brown-red by ferric chloride or nitrous acid, depositing black flocks after some time.

Hydriodide of diamidosalicylic acid, $C^7H^4N^2O^3.2HI + 1\frac{1}{2}H^2O$, is very soluble in water and alcohol, more stable in presence of free hydriodic acid than in neutral solution, and crystallises in faintly yellowish rhombic tables. The *hydrochloride*, $C^7H^4N^2O^3.2HCl$, forms square prisms easily soluble in water, less soluble in alcohol. The *sulphate*, $C^7H^4N^2O^3.SO^2H^2 + H^2O$, separates on adding sulphuric acid to an alcoholic solution of the hydriodide, in stellate groups of square prisms slightly soluble in water, nearly insoluble in alcohol. The *nitrate* has been obtained only in groups of black crystals (Saytzeff, *Ann. Ch. Pharm.* cxxxiii. 321).

Diazosalicylic acid, $C^7H^4N^2O^3$, separates on passing nitrous acid into an alcoholic solution of the hydrochloride of amidosalicylic acid, in slender needles, which may be recrystallised from hot alcohol, but are decomposed by long boiling, with evolution of nitrogen and formation of salicylic acid. It dissolves in moderately concentrated hydrochloric, hydrobromic, or nitric acid, the solutions on cooling depositing crystalline compounds of these acids with diazosalicylic acid; heated with hydriodic acid, it is converted, with rapid evolution of nitrogen, into iodosalicylic acid. The *hydrochloride*, $C^7H^4N^2O^3.HCl + H^2O$, crystallises in long prisms which are decomposed by water, leaving diazosalicylic acid. Platinic chloride added to the solution of the hydrochloride

throws down the platinum salt, $2(C^6H^4N^2O^3.HCl).PtCl_4$, which is likewise decomposed by water, and when heated to about 200° , it yields a sublimate of *monochloro-salicylic acid*, $C^6H^3ClO^3$, in long needles resembling benzoic acid (Schmitt).

Oxysalicylic Acid. $C^6H^4O^4$.—This acid, prepared by Lautemann's process (iv. 320), dissolves in 58.7 pts. of water at 21° , much more freely in hot water; melts at 183° (193° according to Lautemann); reduces ammoniacal silver solution even in the cold; precipitates cuprous oxide from Fehling's solution when heated; and forms with ferric chloride a blue liquid turned blood-red by ammonia (Liechti, *Zeitschr. f. Chem.* [2] vi. 197).

Ethyl oxysalicylate, $C^6H^3O^4.C^2H^5$, obtained by passing hydrochloric acid gas into an alcoholic solution of the acid, and purified by recrystallisation from boiling carbon bisulphide, crystallises from the latter in tufts of colourless, inodorous laminae. It melts at 78° ; cannot be sublimed; dissolves very easily in alcohol and ether; water dissolves a small quantity of it, but very slowly and only after it has deliquesced. It reduces silver nitrate and Fehling's copper-solution; colours ferric chloride dark blue, changing to yellow, and on warming to brown-red; forms with lead acetate a white precipitate soluble in acetic acid. It is decomposed by ammonia, yielding products which have not been accurately investigated (Liechti).

Derivatives of Salicylic Acid containing Alcohol-radicles.

Salicylic acid, having the constitution represented by the formula $C^6H^4 \begin{Bmatrix} OH \\ COOH \end{Bmatrix}$ is capable of forming two classes of acid ethers, accordingly as the hydrogen of the hydroxyl or of the carboxyl is replaced by an alcohol-radicle, and neutral ethers in which both these hydrogen-atoms are thus replaced; e.g.,

Methyl-salicylic Acid. $C^6H^4 \begin{Bmatrix} OCH^3 \\ CO^2H \end{Bmatrix}$ (Graebe, *Ann. Ch. Pharm.* cxxxvi. 124; cxxxix. 134).—Obtained by heating 1 pt. of winter-green oil (acid methyl salicylate*) with $\frac{1}{2}$ pt. potassium hydrate (previously dissolved in alcohol) and $1\frac{1}{2}$ to 2 pts. methyl iodide in a closed vessel to 100° – 120° for several hours, and decomposing the resulting liquid (decanted from the potassium iodide and freed from excess of methyl iodide) by boiling with caustic soda. On adding hydrochloric acid, methyl-salicylic acid separates, and may be freed from admixed salicylic acid by recrystallisation, or by digestion with milk of lime, whereby calcium salicylate is separated in the insoluble state.

Methyl-salicylic acid crystallises, by slow evaporation of its alcoholic solution, in well-defined prisms, which, according to Rammelsberg's determinations, appear to be monoclinic, exhibiting the combination $\infty P. \infty P. \infty. (\infty P. \infty). (P. \infty). 0P$. It dissolves very easily in alcohol and ether, and in about 200 pts. of water at 20° , much more easily in boiling water. The solution has an acid reaction, and is not coloured violet by ferric chloride. The acid melts at 98.5° , under water at 72° . Above 200° it is resolved into anisol (methyl-phenol) and carbon dioxide. Heated with hydriodic acid to 120° – 130° , it yields salicylic acid and methyl iodide, and decomposes in a similar manner with hydrochloric acid:

Barium methylsalicylate, $(C^6H^3O^3)^2Ba$, is very soluble, and forms a nodular crystalline mass. The calcium salt is slightly soluble in cold water, and crystallises from hot water in large needles. The lead salt, $(C^6H^3O^3)^2Pb + H^2O$, forms tufts of sparingly soluble prismatic crystals. The silver salt, $C^6H^3O^3Ag$, is a white precipitate, and crystallises from water in stellate groups of needles. The ethylic ether, $C^6H^4(OCH^3).CO^2C^2H^5$, formed by Cahour's process (v. 160), or by passing hydrochloric acid gas into an alcoholic solution of the acid, boils at 260° (Graebe).

Methyl-nitrosalicylic acid, $C^6H^4(NO^2) \begin{Bmatrix} OCH^3 \\ CO^2H \end{Bmatrix}$, produced by adding methyl-salicylic acid to fuming nitric acid, forms slender colourless needles melting at 149° , solidifying in the crystalline form on cooling, subliming without decomposition, sparingly soluble in cold, easily in boiling water, also in alcohol and ether; does not reddens ferric chloride (Kraut).

The acid methyl-ethers of nitro- and dinitro-salicylic acid are formed, with evolution

* The same methyl-salicylic acid applied to winter-green oil in vol. v. p. 1005 is incorrect.

of nitrogen dioxide, by the action of nitrogen tetroxide (nitroso-nitric anhydride) on winter-green oil; e.g.,

and

(Bunge, *Zeitschr. f. Chem.* [2] iv. 649).

Ethyl-salicylic Acid, $\text{C}^6\text{H}^4\text{O}^3 = \text{C}^6\text{H}^4\left\{\begin{array}{l} \text{OC}^2\text{H}^5 \\ \text{CO}^2\text{H} \end{array}\right.$ —The methylic ether of this acid, $\text{C}^6\text{H}^4(\text{OC}^2\text{H}^5) \cdot \text{CO}^2\text{CH}^3$, is prepared by heating winter-green oil with equivalent quantities of potassium hydrate and ethyl iodide, or by first converting the winter-green oil into methylic sodium-salicylate, $\text{C}^6\text{H}^4(\text{ONa}) \cdot \text{CO}^2\text{CH}^3$, by treating it with an equivalent quantity of caustic soda mixed with several times its volume of saturated solution of common salt, and heating this sodium compound with ethyl iodide in sealed tubes. When washed with dilute potash, dried, and rectified, it boils at 265° . To obtain ethyl-salicylic acid, the methylic ether is converted into a barium salt by prolonged boiling with baryta-water; this salt, after recrystallisation from alcohol, is decomposed by hydrochloric acid; and the acid thus separated is dissolved out by ether. Ethyl-salicylic acid is a colourless, scentless oil, conglutating at -16° to a viscid, nearly solid mass, which, on being removed from the freezing mixture, separates into crystals melting at 19.3 to 19.5° . Its *barium salt*, $(\text{C}^6\text{H}^4\text{O}^3)^2\text{Ba}$, is very soluble in water, crystallises from absolute alcohol in interlaced needles, and is precipitated from the alcoholic solution by ether. The *calcium salt*, $(\text{C}^6\text{H}^4\text{O}^3)^2\text{Ca}$, crystallises from water in microscopic needles. The *lead salt*, $(\text{C}^6\text{H}^4\text{O}^3)^2\text{Pb} + 2\text{H}^2\text{O}$, forms slender needles which melt and give off their water at 150° . The *silver salt*, $\text{C}^6\text{H}^4\text{O}^3\text{Ag}$, is a white precipitate crystallising from water in tufts of needles (Kraut, Schröder, a. Prinzhorn, *Ann. Ch. Pharm.* cl. 1).

Ethyl-nitrosalicylic acid, $\text{C}^6\text{H}^4(\text{NO})^2\text{O}^3 = \text{C}^6\text{H}^4(\text{NO})^2\left\{\begin{array}{l} \text{OC}^2\text{H}^5 \\ \text{CO}^2\text{H} \end{array}\right.$, is obtained by evaporating ethyl-salicylic acid with nitric acid of sp. gr. 1.2 and recrystallising from boiling water, or by heating acid methyl-nitrosalicylate (nitrated winter-green oil) with potash and ethyl iodide, saponifying the resulting methylic ether with potash, and removing unaltered nitrosalicylic acid in the form of basic barium salt. Ethyl-nitrosalicylic acid crystallises from boiling water in colourless silky laminae; melts at 161 ; solidifies in the crystalline form on cooling; sublimes without decomposition; does not colour ferric chloride; is nearly insoluble in cold water, but easily soluble in boiling water, also in alcohol and ether. It is isomeric with the acid ethyl-nitrosalicylate, crystallising in yellow needles, prepared by Cahours (v. 166; there called ethyl-nitrosalicylic acid), and probably identical with the acid which Perkin obtained from ethyl-salicyl (p. 1009). The *barium salt*, $[\text{C}^6\text{H}^4(\text{NO})^2\text{O}^3]^2\text{Ba} + 2\text{H}^2\text{O}$, forms colourless, shining, short prisms, often united in crosses, moderately soluble in cold water. The *silver salt* is a white precipitate crystallising from boiling water in needles (Kraut, Schröder, a. Prinzhorn).

Isopropylsalicylic acid, $\text{C}^6\text{H}^4\text{O}^3 = \text{C}^6\text{H}^4\left\{\begin{array}{l} \text{OCH}(\text{CH}^3)^2 \\ \text{COOH} \end{array}\right.$, prepared like the ethyl-compound, is a transparent, colourless oil becoming viscid, but not solid, at -20° ; neither does it solidify when left for a long time over oil of vitriol. It has a strong acid reaction; mixes with alcohol and ether; is nearly insoluble in cold, somewhat more soluble in boiling water, the solution becoming milky on cooling; does not colour ferric chloride. The *calcium salt*, $(\text{C}^6\text{H}^4\text{O}^3)^2\text{Ca} + 2\text{H}^2\text{O}$, forms tufts of slender needles very soluble in hot water. The *barium salt*, $(\text{C}^6\text{H}^4\text{O}^3)^2\text{Ba} + \text{H}^2\text{O}$, separates as a gum from aqueous solution, in needles from an alcoholic solution covered with a layer of ether. The *silver salt*, $2\text{C}^6\text{H}^4\text{O}^3\text{Ag} + \text{H}^2\text{O}$, crystallises from boiling water in tufts of needles. The *methylic ether*, $\text{C}^6\text{H}^4\text{O}^3 \cdot \text{CH}^3$, obtained by heating winter-green oil with isopropyl iodide and alcoholic potash, is an oil having a faint yellow colour, becoming darker on exposure to light; boils at 250° ; sp. gr. 1.062 at 20° ; dissolves easily in alcohol and ether; does not colour ferric chloride. Heated with alcoholic ammonia, it is converted into the amide $\text{C}^6\text{H}^4\text{O}^2 \cdot \text{NH}^2$, which crystallises in feathery needles, soluble in aqueous ammonia or potash, in alcohol and ether; melts in moderately warm water and dissolves therein (Kraut, Schröder, a. Prinzhorn).

Benzyl-salicylic acid, $\text{C}^6\text{H}^3(\text{C}^6\text{H}^5)\text{O}^3 = \text{C}^6\text{H}^3(\text{OC}^6\text{H}^5) \cdot \text{CO}^2\text{H}$, is formed by heating benzoyl chloride with methyl sodium-salicylate and alcohol in a sealed tube

to 100°. The resulting liquid evaporated over the water-bath leaves an oil which distils above 320°; and by boiling this oil with alcoholic potash, dissolving the resulting potassium salt in water, and adding hydrochloric acid, benzyl-salicylic acid is obtained as an oil, which solidifies in the course of 24 hours, and may be recrystallised from alcohol, or better from carbon tetrachloride. It melts at 75°, dissolves easily in alcohol, crystallises therefrom in small transparent plates, and is somewhat soluble in boiling water. Its *ammonium salt* is decomposed by evaporation. The *silver salt*, $C^{11}H^{10}O^3Ag$, is a white precipitate, melting at 100°. The *lead* and *mercury salts* are white, the *copper salt* is a pale apple-green precipitate (Perkin, *Chem. Soc. J.* vi. 122).

Derivatives of Salicylic Acid containing Organic Acid Radicles.

Acetyl-salicylic acid, $C^8H^6O^4 = C^8H^4 \left\{ \begin{smallmatrix} OC^2H^3O \\ CO^2H \end{smallmatrix} \right\}$, first obtained by Gilm (*Ann.*

Ch. Pharm. cxii. 180), by the action of acetyl chloride on salicylic acid, is likewise formed by the action of acetyl chloride on sodium salicylate, in which case Gerhardt supposed acetosalicylic anhydride to be formed (*ibid.* lxxxviii. 162); it may be extracted from the product by ether, and remains, after the distillation of the latter, as a nearly colourless oil which quickly crystallises. It separates from boiling water in very loosely aggregated slender needles; has a strong acid reaction; melts when heated, and resolidifies in the crystalline form if it has not been heated above its melting point; the recently fused acid solidifies at 118°–118.5°. It dissolves very sparingly in cold water; melts when heated under water, and is not perceptibly decomposed by prolonged boiling with water; dissolves easily in alcohol, ether, and benzol; colours ferric chloride like salicylic acid; decomposes carbonates; is precipitated by acids without alteration. With excess of hot baryta-water it yields salicylate and acetate. When heated with ammonia it forms ammonium salicylate, and probably acetamide, but no salicylamide (salicylamide is not converted into ammonium salt under the conditions just mentioned) (Kraut, Schröder, a. Prinzhorn).

Salicylosalicylic or Disalicylic acid, $C^{11}H^{10}O^5 = \left\{ \begin{smallmatrix} (C^7H^5O)^2 \\ H^2 \end{smallmatrix} \right\} O^3$ or

$O-C^6H^4-CO^2H$
 $\quad \quad \quad |$
 $O=C-C^6H^4-OH$, also called *Salicylic anhydride* (v. 160), is formed when a mixture of acetyl chloride and salicylic acid is heated for some time to 130°–140° in a flask with upright condenser, and separates as a yellowish oil on boiling the product with water; also, together with acetic anhydride, by heating acetyl-salicylic acid to 140°–170°. It is obtained pure by boiling the oil with water, dissolving the remainder in ether, decolorising with animal charcoal, dehydrating, and evaporating. It then forms a transparent amorphous light yellow mass, which by standing over oil of vitriol, or warming, becomes hard, brittle, and friable, and dissolves easily in alcohol, ether, and benzol. When treated with alkaline carbonates, it forms easily soluble salts, from which it is precipitated by acids in its original state. It is converted by aqueous ammonia into salicylamide and ammonium salicylate, and when further heated, gives off 1 mol. water, and leaves trisalicylosalicylic acid, $C^{28}H^{16}O^9$, according to the equation: $2C^{11}H^{10}O^5 = H^2O + C^{28}H^{16}O^9$.

Trisalicylo-salicylic or Tetrasalicylic acid, $C^{28}H^{16}O^9 = 4 \left\{ \begin{smallmatrix} (C^7H^5O)^2 \\ H^2 \end{smallmatrix} \right\} O^3$ or $HO-(C^6H^4)^2-(COOC^6H^4)^2-(COOC^6H^4)^2-(COOC^6H^4)^2-COOH$.—This compound, obtained, as just mentioned, by dehydration of disalicylic acid, is also formed when acetosalicylic acid is heated as long as acetic anhydride continues to go off, and till the temperature has risen to 230°–240°, and a drop of the distillate becomes turbid when mixed with a little water. The viscid residue may then be purified in the same manner as the preceding compound. Tetrasalicylic acid is a thick light yellow oil, which becomes hard and brittle much more quickly than disalicylic acid; softens at about 70°; reacts with solvents, caustic potash, alkaline carbonates, and ammonia, like disalicylic acid; and when further heated, yields salicylic acid, phenol, carbon dioxide, and a body, C^8H^4O , formerly obtained by Limpricht and by Märcker from salicylide (v. 161).

Heptasalicylo-salicylic or Octosalicylic Acid, $C^{54}H^{28}O^{17} = \left\{ \begin{smallmatrix} (C^7H^5O)^2 \\ H^2 \end{smallmatrix} \right\} O^8$ or $HO-(C^6H^4)^7-(COOC^6H^4)^7-COOH$.—Prepared by heating 1 pt. phosphorus

oxychloride with 2 or 3 pts. of finely pulverised sodium salicylate to 150° in a flask with upright condenser, till the whole is converted into a viscid mass; expelling the excess of oxychloride in a stream of dry air at 110° ; boiling with dilute solution of sodium carbonate, then with water; digesting the dried residue with ether to remove a small quantity of disalicylic acid; again drying the residue, and dissolving it in boiling benzol; pouring the concentrated solution into a large quantity of absolute alcohol; immediately collecting the amorphous flocks which separate on a filter; and freeing them from benzol and alcohol by leaving them over oil of vitriol frequently renewed. Octosalicylic acid thus prepared is a loose white powder, becoming strongly electrical by friction; insoluble in water, ether, and cold alcohol, somewhat soluble in boiling alcohol, easily in benzol; solidifying after fusion to a brittle resin. Heated for three hours to 200° – 220° in a stream of hydrogen, it loses 7.2 p. c. of its weight, yielding carbon monoxide, and a sublimate consisting of salicylic acid and the body C^8H^4O , but no water, and leaving unaltered octosalicylic acid. The formation of octosalicylic acid is represented by the equation $8C^8H^4O^3 - 7H^2O = C^8H^4O^{17}$; it is probably identical with salicylide (v. 161) (Kraut, Schröder, a. Prinzhorn).

SALICYLOL. $C^7H^4O^2 = C^7H^3\begin{Bmatrix} OH \\ CHO \end{Bmatrix}$. *Salicyl Hydride. Salicylic Aldehyde.*—

This compound is obtained, according to E. W. Davy (*Laboratory*, p. 361), by distilling poplar-twigs which have lain for some time exposed to the air.

Salicylol is converted by *phosphorus pentabromide* at ordinary temperatures into monobromosalicylol, $C^7H^3BrO^2$, which crystallises in tufts of dentated scales or laminae melting at 98° – 99° . *Pentachloride of phosphorus* acts differently, producing dichlorocresol, $C^7H^2Cl^2O$ (L. Henry, *Zeitschr. f. Chem.* [2] v. 371, 478).

Salicylol unites directly with *acetic anhydride*. A mixture of the two heated for four or five hours to 150° becomes perfectly fluid, but when treated with dilute potash, solidifies to a crystalline mass of the compound $C^7H^4O^2.C^4H^4O^2$. This compound crystallises from alcohol in thick transparent plates with bevelled edges; melts at 103° – 104° ; distils with partial decomposition; is insoluble in water, sparingly soluble in cold, easily in boiling alcohol; and when heated with water to 150° , is resolved into acetic acid and salicylol. Cold potash does not act upon it. The solution in nitric acid deposits salicylol in the form of an oil, on addition of water. *Methyl-, ethyl-, and acetyl-salicylol* also unite directly with acetic anhydride, forming crystalline compounds (Perkin, *Chem. Soc. J.* [2] v. 586).

Salicylol is an alcoholic aldehyde, as indicated by the formula above given, and its alcoholic hydrogen may be replaced by alkali-metals, alcohol-radicles, and organic acid radicles.

Sodium-salicylol. $C^7H(ONa).CHO$, originally obtained by the action of sodium on salicylol in aqueous solution (v. 169), is more conveniently prepared by treating salicylol with sodium ethylate. Sodium is dissolved in 20 to 30 times its weight of absolute alcohol, and the hot solution is mixed with an equivalent quantity of salicylol, whereupon sodium salicylol immediately begins to separate in golden-yellow laminae, which may be purified by washing with a little alcohol (Perkin, *Chem. News*, xviii. 110).

Cupric salicylol is decomposed by cyanogen chloride in aqueous solution, yielding salicylol, cupric chloride, and cyanic acid, which is immediately transformed into ammonium carbonate:

But when gaseous cyanogen chloride is passed over cupric salicylide heated to 100° – 120° , cupric cyanide is formed, together with an oil which solidifies on cooling to a mass of silky needles, consisting of chlorosalicylol, $(C^7H^3O^2)^2Cu + 2CyCl = CuCy^2 + 2C^7H^3ClO^2$ (Schiff, *Ann. Ch. Pharm.* cl. 199).

Alcoholic Derivatives of Salicylol.

Methyl-salicylol, $C^8H^4(OCH^3).CHO$, isomeric with anisaldehyde, is formed by heating pulverised sodium-salicylol for two or three hours with rather more than an equal weight of methyl iodide and 2 or 3 mol. alcohol to 135° – 140° , and separates on mixing the contents of the tube with water, as a nearly colourless oil, which, after washing with weak potash-solution, distils at 288° . It has a faint odour; is heavier than water, nearly insoluble therein; does not solidify in a freezing mixture; gives off hydrogen when treated with sodium; forms crystallisable, easily soluble compounds with the acid sulphites of alkali-metal. Treated with *bromine* in excess, it is converted into methyl-bromosalicylol, $C^8H^3Br(OCH^3).CHO$, a white solid mass, which crystallises from hot alcohol in flat prisms melting at 113° – 114.5° . A

mixture of methyl-salicylol and alcoholic ammonia becomes syrupy in 24 hours, and yields on evaporation a viscid product perhaps analogous to hydrobenzamide, which is converted at 160° – 170° into a base. The solution of methyl-salicylol in nitric acid of sp. gr. 1.4 separates, on addition of water, a dark-coloured heavy oil, which by further treatment with nitric acid is converted into a solid nitro-acid (Perkin, *Chem. Soc. J.* [2] v. 418).

Ethyl-salicylol, $C^8H^{10}O^2 = C^8H^7(OC^2H^5).CHO$, prepared like the methyl-compound, is a nearly colourless, heavy, strongly refracting oil, having a faint odour, boiling at 247° – 249° , not solidifying at low temperatures, nearly insoluble in water, miscible in all proportions with alcohol and ether; it does not unite with alkalis, but forms crystalline compounds with alkaline bisulphites. The sodium salt, $C^8H^{10}O^2 \cdot SO^2HNa$, crystallises from warm alcohol in silky needles, from water in long efflorescent prisms, is decomposed by heating to 100° , also by hydrochloric acid and by potash. With bromine ethyl-salicylol forms ethyl-bromosalicylol, $C^8H^{12}Br(OC^2H^5).COH$, which crystallises from alcohol in flat oblique prisms, melts at 67° – 68° , and forms a crystalline compound with acid sodium sulphite (Perkin, *loc. cit.*).

A solution of ethyl-salicylol in alcoholic ammonia gradually deposits a viscid oil which crystallises on standing and consists of hydro-ethylsalicylamide, $C^8H^{10}N^2O^3$, formed according to the equation:

This compound dissolves sparingly in cold, more easily in hot alcohol, and crystallises therefrom, with partial decomposition, in small oblique prisms; melts at 100° ; solidifies to a resinous mass; dissolves in hydrochloric acid, not in cold potash-ley; and is converted at 160° – 165° into an amorphous isomeric base, ethyl-salidine. This base is very bitter, and forms a platinochloride, $2(C^8H^{10}N^2O^3 \cdot HCl).PtCl_4$, which is deposited from its alcoholic solution on evaporation as a pale orange-yellow crystalline powder (Perkin).

Fuming nitric acid converts ethyl-salicylol into a dark yellow oil precipitable by water—probably ethyl-nitrosalicylol—which by further treatment with nitric acid is converted into ethyl-nitrosalicylic acid, $C^{11}H^7(C^2H^5)(NO^2)O^2$. This acid crystallises from alcohol in large pale yellow prisms, melts at 163° , and has a strong acid reaction. Its silver salt is a pale yellow precipitate.

Allyl iodide heated to 160° with sodium-salicylol and alcohol, forms an oily product. With amyl iodide an oil is likewise obtained, which forms a crystallisable compound with sodium bisulphite (Perkin).

Benzyl-salicylol, $C^{14}H^{12}O^2 = C^{14}H^9(OC^6H^5).CHO$, isomeric with benzoin, is produced by heating a mixture of equivalent quantities of sodium-salicylol and benzyl chloride with several times its volume of alcohol to 120° – 140° ; filtering from sodium chloride; evaporating; distilling the remaining oily liquid, the greater part of which passes over above 32° ; washing the oily distillate with potash-solution, and then agitating it with a strong solution of sodium bisulphite, with which it slowly forms a crystalline compound. These crystals are dissolved in cold water; the solution freed from oily impurities by ether is mixed with sodium carbonate; and the body thereby separated is dissolved in ether, and obtained by evaporation as a viscid oil, which gradually solidifies on agitation, and may be purified by recrystallisation from alcohol. Benzyl-salicylol thus obtained melts at 46° , and boils at a temperature above the range of the mercurial thermometer. When cold it has a faint aromatic odour, like that of cloves; when heated it emits a pungent suffocating odour. It is soluble in ether, carbon-tetrachloride, benzol, and alcohol, from which it crystallises in transparent flat oblique rhombic prisms. It dissolves sparingly in boiling water, and with yellow colour in sulphuric acid and alcoholic potash-solution. It is attacked by bromine and nitric acid, unites with alkaline bisulphites, and forms an oily product when heated with acetic anhydride (Perkin, *Chem. Soc. J.* [2] vi. 122).

Acetyl-salicylol. $C^8H^8O^3 = C^8H^5 \begin{Bmatrix} OC^2H^3O \\ CHO \end{Bmatrix}$ (Perkin, *Chem. Soc. J.* [2] vi. 53, 181).—This compound, isomeric with coumaric acid, is produced by adding acetic anhydride to pulverised sodium-salicylol suspended in dry ether, decanting the ethereal solution after 24 hours from the sodium acetate produced, and evaporating it over the

* A body having this composition was described by Cahours as obtained by the action of acetyl chloride on salicylol (v. 176). Schüler however did not succeed in preparing it in this way (*Jahresb.* 1867, p. 317); and Perkin (*ibid.* 1867, p. 433) obtained thereby, not acetyl-salicylol, but di-salicylol or para-salicylol (p. 1611). Moreover, the compound obtained by Cahours does not agree in its properties with that produced by the action of acetic anhydride on salicylol.

water-bath. Acetosalicylol then remains in the form of an oil which soon solidifies to a crystalline mass; its formation is represented by the equation:

Acetyl-salicylol melts at 37°, and resolidifies to a satiny crystalline mass; boils at about 253°, and distils with slight decomposition. It dissolves easily in ether and in alcohol, and crystallises therefrom in silky needles; the solutions do not colour ferric chloride purple. By *potash* it is resolved into potassium acetate and potassium salicyllo:

whereas coumaric acid similarly treated yields acetate and salicylate of potassium, with evolution of hydrogen:

Acetyl-salicylol is decomposed by boiling with *water*. It unites with *acetic anhydride* when the two are heated together to 150°, forming a crystalline compound, $C^6H^4O^3$, $C^2H^3O^3$, analogous to that of salicyllo (p. 1000). This compound melts at 100°–101°, decomposes when distilled, and separates from solution in acetic anhydride in oblique four-sided tables. It is soluble in ether, carbon tetrachloride, and benzol, easily soluble in hot, sparingly in cold alcohol. By water at 150° it is completely resolved into acetic acid and salicyllo.

If instead of adding acetic anhydride to sodium salicyllo suspended in ether, and decanting from the sodium acetate as above described, the sodium salicyllo be dissolved in acetic anhydride, the solution boiled for a few minutes, and then poured into water, an oily body separates, while sodium acetate remains in solution. On distilling this oil, acetic anhydride passes over first, then salicyllo, and finally at 290° coumarin, $C^6H^4O^2$, which crystallises in the receiver. This compound results from dehydration of acetyl-salicyllo formed in the first instance: $C^6H^4O^3 - H^2O = C^6H^4O^2$; and its formation appears to depend upon the presence of sodium acetate, inasmuch as acetic anhydride alone produces only acetyl-salicyllo. Perhaps the anhydride-acetate, $C^2H^3O^2Na$, $C^6H^4O^3$ (which Perkin has obtained in needle-shaped crystals by dissolving sodium acetate in acetic anhydride), plays some unexplained part in this reaction.

Butyric coumarin, $C^{11}H^{10}O^2$, and *valeric coumarin*, $C^{12}H^{12}O^2$, are obtained in like manner by the action of butyric and valeric anhydrides on sodium-salicyllo (p. 500).

Butyryl-salicyllo. $C^{11}H^{12}O^3 = C^6H^4 \begin{Bmatrix} OC^4H^7O \\ COH \end{Bmatrix}$ (Perkin, *Chem. Soc. J.* [2] vi.

472).—Prepared by leaving an ethereal solution of butyric anhydride in contact with sodium-salicyllo for two or three days, then decanting from the sodium-butyrate, and proceeding as in the preparation of the preceding compound. It distils between 260° and 270°, as an oil smelling like butyric acid and salicyllo. It is quickly decomposed by strong *potash-solution*, yielding potassium butyrate and potassium salicyllo. On heating it to 140°–150° with *acetic anhydride*, and leaving the slightly brown mass in contact with water for two days, crystals are obtained having the composition $C^{11}H^{14}O^6$, and identical with the above-described compound of acetosalicyllo with acetic anhydride; an interchange of the radicles acetyl and butyryl must therefore have taken place.

When a mixture of butyrosalicyllo, butyric anhydride, and sodium butyrate is heated to boiling for a short time in an open vessel, then washed with water and distilled, the last third of the distillate solidifies on cooling, and when recrystallised from alcohol, yields pure butyric coumarin, $C^{11}H^{10}O^2 = C^{11}H^{12}O^3 - H^2O$; and this compound boiled with potash is converted into butyric-coumaric acid, $C^6H^4 \begin{Bmatrix} C^4H^7O \\ COOH \end{Bmatrix}$, isomeric with butyrosalicyllo. (See COUMARIN and COUMARIC ACID, pp. 500, 501.)

Benzoyl-salicyllo. $C^{14}H^{10}O^3 = C^6H^4 \begin{Bmatrix} OC^2H^3O \\ COH \end{Bmatrix}$ (Perkin, *Laboratory*, i. 51;

Zeitschr. f. Chem. 1867, p. 346).—Produced by the action of benzoyl chloride on sodium-salicyllo, and separates on treating the product with water, as a thick oil, which distils at a temperature above the range of the mercurial thermometer. It forms a white pulverulent compound with acid sodium sulphite, and crystalline compounds with the acid sulphites of potassium and sodium. Heated with alcoholic potash it yields benzoic acid and salicyllo; with alcoholic ammonia it forms a brown viscid product, together with a crystalline body:

When salicylol is mixed with an equal weight of acetyl chloride, a large quantity of hydrochloric acid is evolved, and the liquid on cooling deposits hard prisms, which when purified by recrystallisation have the composition $C^{14}H^{10}O^2$. The compound thus formed is therefore isomeric with benzoyl-salicylol; it is identical with Ettling's parasalicyl (v. 170), and is regarded by Perkin as disalicylol, its formation taking place in the manner represented by the equation:

The same body is formed by the action of benzoyl chloride (v. 170) and of succinyl chloride on salicylol. It does not unite with alkaline bisulphites, and when heated to 150° with acetyl chloride, is converted into a non-distillable oil, which appears to contain chlorine and acetyl, and is decomposed by boiling potash-ley, with formation of salicylol.

SALICYLOL, AMIDES and UREIDES OF (Schiff, *Zeitschr. f. Chem.* [2] iv. 636; *Ann. Ch. Pharm.* cl. 193).—Salicylol and ethyl-salicylol are acted upon by organic bases at ordinary temperatures, with rise of temperature and elimination of water.

Aniline forms the two compounds:

Amylamine forms two corresponding hydramylamides. With *ethylaniline* the two following anilides are obtained:

All these anilides are yellow liquids, of aromatic odour, insoluble in water, soluble in alcohol and ether, and destitute of basic properties; they do not form platinumchlorides. When exposed to the air, they quickly turn brown, and after a while, especially the ethylic derivatives, assume a deep emerald-green colour.

In cupric salicylol, $(C^6H^3O^2)_2Cu$, the copper replaces the alcoholic hydrogen, the compound retaining its aldehydic properties. Aniline, amylamine, and fused toluidine act upon this compound, with elimination of water; and the product, after washing with water and alcohol, leaves a green shining crystalline mass, which, in the case of aniline and of amylamine, exhibits the composition represented by the following formulæ:

Ethyl-aniline does not act on cupric salicylol. Toluylene-diamine on the other hand acts upon it at 100° , forming a compound which may be represented as

When salicylol acts upon urea, either in aqueous solution or in the fused state, the first or second of the following salicyl-ureides is produced:

The diureide forms colourless prisms containing 1 mol. water, which is given off in a vacuum. The triureide is a yellow crystalline powder resembling hydrosalicylamide. This latter body is formed, together with cyanuric acid, when the salicyl ureides are heated above their boiling points. The solutions of these ureides form with cupric acetate, olive-green crystalline precipitates consisting of:

Alcoholic ethyl iodide decomposes these copper-derivatives at 100°, forming the corresponding ethyl-derivatives, which however were not obtained pure by this process. The ethylic diureide has however been prepared in the pure state by the action of ethyl-salicyl on urea in aqueous solution. It has the composition

The molecule of water is given off at 100°, with partial decomposition.

SALICYLONITRILE. $\text{C}^7\text{H}^3\text{NO} = \text{C}^6\text{H}^4 \left\{ \begin{array}{l} \text{OH} \\ \text{CN} \end{array} \right.$ *Salicylimide*.—This compound (or a polymeride of it), discovered by Limpricht (v. 166), is produced by heating salicylamide, $\text{C}^7\text{H}^3\text{NO}_2$, to 270°–300° for several hours, and may be purified by washing with boiling water and recrystallisation from carbon bisulphide or oil of turpentine. It is nearly insoluble in alcohol, ether, benzol, and chloroform, dissolves more easily in carbon bisulphide, and in about 200 pts. of boiling oil of turpentine. It dissolves without alteration in strong sulphuric acid, also in aqueous or alcoholic potash, and is precipitated from the alkaline solution by acids; but by fusion with potassium hydrate it is resolved into salicylic acid and ammonia. It melts at 280°–285°, sustains without decomposition a temperature of more than 350°, and sublimes in small portions in the form of a yellow crystalline powder. It takes up bromine, with elimination of hydrobromic acid, and the brominated product, heated with a quantity of potash-solution not sufficient to decompose it completely, is converted into a scarlet powder. A similar red compound is sometimes obtained with non-brominated salicylonitrile. The great stability of the compound obtained by heating salicylamide seems to show that it is rather a polymeride of salicylonitrile than that compound itself. To obtain the latter, salicylamide was fused with phosphoric anhydride, whereby a white substance was formed, melting at 195°, insoluble in water, soluble in alcohol, and easily resolved by aqueous potash into salicylic acid and ammonia, but it has not yet been obtained pure (Grimaux, *Bull. Soc. Chim.* [2] xiii. 25).

Benzoyl-salicylonitrile, $\text{C}^6\text{H}^4 \left\{ \begin{array}{l} \text{OC}^7\text{H}^3\text{O} \\ \text{CN} \end{array} \right.$ (called by Limpricht, benzoylsalicylamide), is produced by gently heating salicylonitrile with benzoyl chloride, and after solution in boiling alcohol and treatment with animal charcoal, forms small white laminae, melting at 148°–149°, sparingly soluble in cold, more easily in boiling alcohol, very slightly soluble in water. The alcoholic solution prepared with aid of heat is coloured red by ferric chloride (L. Henry, *Zeitschr. f. Chem.* [2] vi. 53).

SALIGENIN and SALIRETIN. Saligenin, $\text{C}^7\text{H}^3\text{O}_2$, is formed, together with glucose, when an aqueous solution of salicin is exposed to the air. Heated in aqueous solution to 100°, it is converted into saliretin, $\text{C}^7\text{H}^3\text{O}$, or rather $\text{C}^6\text{H}^4\text{O}_2$, which separates as a resin (Moitessier, *Jahresh.* 1866, p. 676).

Acetyl-saliretin, $\text{C}^6\text{H}^4(\text{C}^2\text{H}^3\text{O})\text{O}_2$, is produced by heating the sodium or lead compound of saligenin with di- or tri-acetylglucose.

SANDAL-WOOD. According to Weidel (*Zeitschr. f. Chem.* [2] vi. 83), the red resin obtained by exhausting the pulverised wood with slightly alkaline water, and precipitating with hydrochloric acid, yields to ether, first a colourless crystalline body, santal, $\text{C}^6\text{H}^4\text{O}_3$, isomeric with piperonal (p. 947), and by further extraction a cinnamon-red crystalline powder, $\text{C}^6\text{H}^4\text{O}^1$ (?), apparently not identical with Meier's santalin (v. 187).

Santal crystallises from hot alcohol in quadrangular iridescent laminae, containing $2\text{C}^6\text{H}^4\text{O}_3 + 3\text{H}^2\text{O}$; it is insoluble in water, slightly soluble in cold alcohol, and when once crystallised does not dissolve easily in ether; the best solvents for it are dilute solutions of caustic potash and soda; ammonia dissolves it but sparingly. By fusion with potash it is converted into protocathechuic acid. The red resin of sandal-wood fused with potash yields, as principal products, pyrocatechin and resorcin.

SANDBERGERITE. A mineral found, together with enargite, in the district of Youli in Peru. It is iron-black with metallic lustre, very brittle, and has a conchoidal fracture. The crystals are hemihedral forms of the regular system (tetrahedrons combined with a scalene icosi-tetrahedron, &c.), and have an indistinct cubic cleavage. Hardness = 4.5 to 4.75; sp. gr. = 4.369. Contains 41.08 p. c. copper,

2.77 lead, 7.19 tin, 2.38 iron, 7.19 antimony, 14.75 arsenic, and 25.12 sulphur (Breithaupt, *Jahresb.* 1866, p. 918).

SANGUINARINE. This alkaloid, to which J. Schiel assigned the formula $C^{12}H^{12}NO^4$, has been re-examined by Naschold (*J. pr. Chem.* cvi 385; *Zeitschr. f. Chem.* [2] vi. 119). Prepared from the root of *Sanguinaria canadensis*, it gave by analysis numbers agreeing with the formula $C^{12}H^{12}NO^4$. The *hydrochloride* prepared by saturating the ethereal solution with dry hydrogen chloride has, after drying in a vacuum, the composition $C^{12}H^{12}NO^4.HCl + H^2O$. The *platinochloride* dried at 100° is $2(C^{12}H^{12}NO^4.HCl).PtCl^4$; the *platinocyanide* precipitated by adding a hot solution of potassium platinocyanide to a solution of the sulphate contains $2(C^{12}H^{12}NO^4.HCy).PtCy^4$. Double *gold* and *mercury salts* of complex constitution were also obtained.

SAPONIN and **SAPOGENIN.** Rochleder, from a renewed investigation of saponin and its products of decomposition (*Zeitschr. f. Chem.* [2] iii. 632), deduces for saponin the formula $C^{22}H^{34}O^{18}$, and for sapogenin, $C^{14}H^{22}O^8$, whence the complete decomposition of saponin would be represented by the equation.

Sapogenin is soluble in alcohol and in ether, and crystallises from the former by slow evaporation in concentric groups of needles. From solution in dilute aqueous potash it is precipitated by stronger potash-ley, as flocculent *potassium-sapogenin*; the solution in alcoholic potash is precipitated by water only when the potash is in excess. When sapogenin is heated with potassium hydrate till decomposition commences, part of it is resolved into acetic acid, butyric acid, and a soft brown substance, and the undecomposed portion when separated by potash melts at 128° , whereas before the treatment with potash it does not liquify at that temperature. The decompositions of saponin formerly mentioned (v. 191) may be explained, in accordance with the composition of sapogenin above given, by supposing that the gelatinous substance resembling quinin is formed simultaneously with 2 molecules of sugar:

and that the second product, distinguished from sapogenin by its easy solubility in alcohol, is a compound of sapogenin with 1 mol. sugar:

The compound obtained by Frémy from saponin, and designated as *esculin acid*, is regarded by Rochleder as $C^{20}H^{32}O^{17}$, and its formation is represented by the equation:

SARCINE. The following method of estimating this substance, together with xanthine, in muscular flesh is given by Neubauer (*Zeitschr. anal. Chem.* vi. 33; *Jahresb.* 1867, p. 880). The aqueous extract of 250 to 500 grms. of finely chopped meat (freed from albumin by heating) is mixed with basic lead acetate, not in excess; the filtrate freed from lead by hydrogen sulphide is evaporated to 5-10 cub. cent.; the creatine in it is determined by a process already described (p. 501); and the mother-liquor, freed from alcohol, diluted to 100-150 c. c., and made strongly alkaline by ammonia, is mixed with an alkaline solution of silver nitrate. The resulting precipitate is washed with ammoniacal water and dissolved in hot nitric acid of sp. gr. 1.1; and the sarcine double salt, $C^8H^{12}NO^4.AgNO^3$, which separates on cooling, is collected on a filter after six hours, washed with water till the acid reaction is removed, and weighed after drying at 100° . From the acid filtrate the xanthine may be precipitated by supersaturation with ammonia, in the form of the compound $C^8H^{12}NO^4.Ag^2O$. By this process Neubauer has found in beef 0.016 to 0.027 p. c. sarcine, in ox-spleen 0.015 p. c., and in extract of meat 0.59 p. c.

SARCOSINE. A compound of this base with zinc chloride, having the composition $2C^8H^{12}NO^4.ZnCl^2$, is obtained as a crystalline precipitate on mixing the alcoholic solutions of pure sarcosine and zinc chloride; it often separates in the first instance as a syrupy precipitate, which gradually becomes crystalline. 1 pt. of this compound dissolves at ordinary temperatures in 2660 pts. absolute alcohol. It dissolves very easily in water, and separates by spontaneous evaporation in compact nodular radio-crystalline masses consisting of microscopic quadratic prisms not containing water of crystallisation (Buliginisky, *Zeitschr. f. Chem.* [2] iv. 287). According to Podkopaew (*ibid.* 731), the aurochlorides of sarcosine and creatinine, which are easily prepared

from the zinc-chlorides, crystallise well, and afford the means of separating the two bases when they occur together.

SARRACENINE. An alkaloïd occurring in the root of *Sarracenia purpurea*. It is bitter, soluble in alcohol and ether, and forms a crystallisable sulphate (St. Martin, *Zeitschr. f. Chem.* [2] ii. 442).

SASSAFRAS OIL (Grimaux a. Ruotte, *Ann. Ch. Pharm.* clii. 88; *Zeitschr. f. Chem.* [2] v. 411).—This oil is a mixture of a lavogyrate hydrocarbon and an optically inactive oxygenated body, together with a small quantity of a phenolic substance, which gives it the power of reducing silver solution. This body may be extracted from the oil by potash, and the alkaline solution mixed with hydrochloric acid deposits a few drops of an oil which smells strongly of eugenic acid and colours ferric chloride green.

The hydrocarbon, safrene, has the composition $C^{10}H^{14}$. Vapour-density, obs. 4.71; calc. 4.7. Boiling point 155° – 157° . Sp. gr. 0.8345 at 0° . Rotating power $[\alpha] = -17.5^{\circ}$.

The portion of the crude oil ($\frac{2}{3}$ of the whole) which passes over in the first distillation between 230° and 236° consists of safrol, $C^{10}H^{10}O^2$, which boils between 231° and 233° , but not constantly, because a small portion of it becomes resinised at the high temperature. Safrol is insoluble in water, is not easily dehydrated by calcium chloride, and for complete purification must be distilled in a stream of dry hydrogen. It smells like sassafras oil; has a sp. gr. of 1.1141 at 0° ; is optically inactive; remains liquid at -20° ; does not unite with acid sulphites of alkali-metal; does not dissolve sodium; does not act on benzoyl chloride even at the boiling temperature of the latter; does not dissolve in alcoholic potash even at 120° , but is converted by that reagent at 180° into a black uncrystallisable resin. With boiling hydriodic acid (at 127°), it forms a thick green iodated oil. It reduces phosphorus pentachloride to trichloride without formation of oxychloride, and is itself converted into a thick tenacious mass, probably *monochlorosafrol*. A similar product is formed on bringing 1 mol. safrol in contact with 1 mol. bromine; but on adding a large excess of bromine, crystalline *pentabromosafrol*, $C^{10}H^4Br^5O^2$, is produced. To prepare this compound, 5 pts. of bromine are added to a solution of 1 pt. safrol in carbon bisulphide. A large quantity of hydrobromic acid is then evolved, and after a few days crystals separate; and by dissolving these in chloroform, washing the solution with potash-ley, and concentrating, pentabromosafrol is obtained in perfectly white rectangular laminae. It melts at 169° – 170° , is but slightly soluble in alcohol and ether even at the boiling heat, dissolves in about 15 pts. of chloroform. Simultaneously with pentabromosafrol there is formed another brominated product melting at 109° .

Nitric acid, even when very dilute, resinises safrol, with formation of oxalic acid. Fuming nitric acid dissolves it, and converts it into a non-crystallisable body, soluble with blood-red colour in alkalis. Safrol is carbonised by heating with zinc chloride, phosphoric anhydride, or sulphuric acid. Melting potash attacks safrol with difficulty, but sassafras oil distilled over melting potash becomes altered in boiling point, the portions which otherwise distil at 230° – 234° , afterwards passing over only at 245° – 250° , and chiefly at 247° – 248° . This distillate has the same percentage composition as safrol.

SCOPARIN. This substance, the yellow colouring matter of *Spartium scoparium* (v. 208), is resolved, like quercetin, by fusion with potassium hydrate, into glucin and protocathecuic acid, perhaps in the manner represented by the equation :

(Hlasiwetz, *Ann. Ch. Pharm.* cxxxviii. 190).

SELENIUM. *Allotropic Modifications.*—Red crystallised selenium, the monoclinic modification soluble in carbon bisulphide (v. 222), is intermediate in specific gravity between the black and red amorphous varieties, and may be regarded as analogous to monoclinic sulphur. Selenium abstracts chlorine from sulphur chloride, $Se^{2}Cl^2$, and forms selenium chloride, $Se^{2}Cl^2$. If the selenium is in excess, selenium sulphide remains behind on distillation, soluble in carbon bisulphide, and crystallising therefrom in red prisms. Selenium in either of its modifications dissolves very freely in the chloride, $Se^{2}Cl^2$, and separates very slowly on cooling. The selenium thus separated, *in the cold*, belongs to the black modification insoluble in carbon bisulphide. It does not, however, form crystals, but a botryoidal mass consisting of small spherules. Carbon tetrachloride mixed with traces of carbon selenide (p. 1016) dissolves red selenium in small quantity, but not the black variety. Red selenium is slightly

soluble in ethyl sulphide, black selenium insoluble. Ethyl selenide, on the other hand, dissolves both modifications in small and apparently equal quantities. Black selenium appears to be analogous to rhombic sulphur; amorphous red selenium to the variety of sulphur insoluble in carbon bisulphide. The varieties of selenium and sulphur thus compared are formed indeed by similar processes; they are converted in like manner into the other modifications by heating and slow or rapid cooling; and lastly, the specific gravities of these two modifications of selenium differ from one another in the same direction as those of the two modifications of sulphur with which they are compared, (Rathke, *Ann. Ch. Pharm.* clii. 181; *Zeitschr. f. Chem.* [2] v. 720).

Crystallised selenium precipitated from selenious acid by potassium bisulphide, and then heated for a week in a drying closet, has a specific heat = 0.08404; selenium separated by the action of the air from solution in potash has the same specific heat = 0.08401. Amorphous selenium obtained by melting and dropping into cold water softens between 40° and 50°. Its specific heat between 25° and 38° is 0.0953; at 50° and above, the specific heat rapidly increases, being 0.1104 at 52°, and 0.1147 at 61° (Bettendorff a. Wüllner, *Zeitschr. f. Chem.* [2] iv. 560).

On the heat of combination of selenium and of hydrogen selenide, see Hautefeuille (*Compt. rend.* lxxviii. 1554; *Zeitschr.* [2] v. 487).

On the action of selenium on hydriodic acid, see IODINE (p. 739).

For the estimation of selenium in organic compounds, Rathke (*loc. cit.*) heats the compound to 200° for several hours in a sealed tube with potassium dichromate and nitric acid of sp. gr. 1.4; then evaporates to dryness; heats the residue with hydrochloric acid to reduce the chromic acid; again evaporates several times over the water-bath with hydrochloric as nearly as possible to dryness, to convert the potassium nitrate into chloride; and finally precipitates the selenium by sulphurous acid. An inconvenience attending this process is the slowness with which the potassium nitrate is decomposed by hydrochloric acid; this, however, may be obviated by using free chromic acid instead of potassium chromate.

Selenic and Selenious Acids. J. Thomsen (*Deut. chem. Ges. Ber.* ii. 598) prepares pure selenious acid by a method depending on the solubility of barium selenite in free selenious acid. Selenium is dissolved in strong nitric acid; the solution is evaporated to dryness; the residue heated till selenious acid begins to sublime, to expel the excess of nitric acid; the residue is dissolved in water; and to the resulting solution, which may contain selenic and sulphuric as well as selenious acids, baryta-water is added till a filtered sample of the liquid no longer gives a permanent precipitate with a few drops of baryta-water. On evaporating the filtrate and subliming the residue, selenious acid is obtained quite free from selenic and sulphuric acids, and much more permanent in the air than the acid prepared in the ordinary way.

To obtain pure selenic acid, the selenious acid prepared as above is dissolved in water and precipitated with silver nitrate or saturated with silver carbonate. The resulting silver selenite, which is nearly insoluble in water, is shaken up with bromine and water, bromine being added at first, and afterwards bromine-water, till the liquid exhibits a faint orange colour. The solution filtered from the silver bromide is then evaporated to the desired degree of concentration. The solution of selenic acid thus prepared is quite free from sulphuric and selenious acids.

Ethylselenious Acid.—When barium ethylsulphate is distilled with potassium selenide, a reddish-yellow liquid is obtained, which, when treated with nitric acid and then with hydrochloric acid, yields only traces of oily selenethyl chloride, but, as principal product, the crystals described by Joy (ii. 544). From the aqueous solution of these crystals, sulphurous acid throws down pure ethyl biselenide, $(C_2H_5)_2Se_2$, boiling at 186°. These crystals, when purified from selenethyl chloride by agitating their aqueous solution with ether, evaporating the remaining aqueous solution over sulphuric acid, and recrystallising from dilute hydrochloric acid, have the composition of hydrochloride of ethyl-selenious acid, $C_2H_5SeO_2H.HCl$. The crystalline compound obtained in like manner by Wöhler and Dean (iii. 991), by treating methyl biselenide with nitric and hydrochloric acids, consists of the analogous compound $CH_3SeO_2H.HCl$ (Rathke).

Respecting unsuccessful attempts made by Rathke to prepare tetraethyl selenide and tetraethyl sulphide, see *Ann. Ch. Pharm.* clii. 208; *Zeitschr. f. Chem.* [2] v. 724.

Selenium Sulphide. The precipitate formed on passing hydrogen sulphide into selenious acid dissolves with reddish-yellow colour in carbon bisulphide, and the solution concentrated till it begins to deposit crystals on cooling, yields by spontaneous evaporation small but well-defined rhombic prisms, having the colour of potassium dichromate, and containing 63.86 p. c. selenium and 35.50 sulphur. By passing

hydrogen selenide mixed with a large excess of hydrogen, first through water, and then through aqueous sulphurous acid, dissolving the resulting precipitate in carbon bisulphide, and submitting the solution to fractional crystallisation, crystals are obtained having the composition $2\text{Se} + \text{S}$, but consisting, not of the pure compound Se_2S , but of a mixture of that compound with SeS^2 and free selenium. The precipitate obtained by passing hydrogen sulphide through selenious acid has the composition $\text{Se} + 2\text{S}$, and consists mainly of SeS^2 , but contains also Se_2S , probably mixed, not with a higher sulphide of selenium, but with free sulphur (Rathke).

Carbon Selenide, CSe^2 , is produced in small quantity by the action of moist vapour of carbon tetrachloride on phosphorus selenide, the nascent hydrogen selenide resulting from the action of the aqueous vapour on the phosphorus selenide acting on the carbon chloride, according to the equation $\text{CCl}_4 + 2\text{H}^2\text{Se} = 4\text{HCl} + \text{CSe}^2$. (See CARBON-COMPOUNDS, p. 408.) When the solution of carbon selenide in carbon tetrachloride thus obtained is mixed with alcoholic potash, it assumes a deep red colour; and on mixing the solution with water, which separates carbon tetrachloride, adding hydrochloric acid, and heating the liquid after some time, a dark solid mass separates from it saturated with an oil. This mass, separated from the watery liquid and distilled in a small bent tube, yields a golden-yellow liquid having an intolerable odour and consisting of *ethyllic selenio-xanthate*, $\text{C}^2\text{H}^5\text{Se}^2\text{O}$. When the liquid containing the carbon selenide is dropped into a concentrated solution of potash in absolute alcohol, *potassium selenio-xanthate*, $\text{C}^3\text{H}^5\text{Se}^2\text{OK}$, separates in yellow, very deliquescent needles, the alkaline aqueous solution of which yields selenide of lead when heated with lead acetate. The solution decolorises a solution of iodine in potassium iodide, becoming turbid at the same time (Rathke).

SENNA. According to Dragendorff a. Kubly (*Zeitschr. f. Chem.* [2] ii. 411), the active principle of senna-leaves is a glucoside, which they designate as *cathartic acid* (p. 417).

SERICIN and **SERIN.** See SILK.

SERICOGRAPHIS MOHITLI. An acanthaceous plant used in Mexico as a remedy for dysentery, and containing a blue colouring matter called *mohillin* (p. 331).

SERPENTINE. For analyses of this mineral from various localities, see *Jahresb. f. Chem.* 1860, 774; 1861, 1004; 1862, p. 745; 1863, p. 856; 1866, p. 931; 1867, pp. 996, 1016, 1026.

SIDEROPLSITE. A carbonate of iron and magnesia occurring near Dienten in Salzburg, in the graywacke formation, in lenticular forms, accompanied by dolomite rhombohedrons and rock crystal. Sp. gr. = 3.699. Angle of terminal edges of the cleavage-rhombohedron = $107^\circ 5' 16''$. Its analysis gave

CO^2	FeO	MnO	MgO	CaO	Fe^2O^3
40.31	43.86	2.57	10.46	0.40	4.07 = 101.67

Reckoning the ferric oxide as ferrous carbonate, the mineral may be represented by the formula $8\text{CO}^2\text{Fe} \cdot 3\text{CO}^2\text{Mg}$ (Zepharovich, *Jahresb.* 1866, p. 906).

SILICA. The constitution of silica (whether SiO^2 or SiO^3) has been discussed by Scheerer (*J. pr. Chem.* xci. 415; *Jahresb.* 1864, p. 310); Ordway (*Sill. Am. J.* [2] xl. 187; *Jahresb.* 1866, p. 192); and Geuther (*Jenaische Zeitschr.* iv. 313; *Jahresb.* 1868, p. 206).

Modifications.—An amorphous silica of sp. gr. 2.6, differing from the ordinary variety (sp. gr. 2.2), is formed, according to Jenzsch (*Pogg. Ann.* cxxvi. 467; *Jahresb.* 1865, p. 875), by the weathering of chalcodony. G. vom Rath (*Pogg. Ann.* cxxviii. 507; cxxxv. 437; *Zeitschr. f. Chem.* [2] iv. 666; v. 410), has discovered in a volcanic porphyry from the Cerro S. Cristobal, near Pachuca in Mexico, a new mineral, which he designates as *tridymite*, consisting of crystallised silica of sp. gr. 2.3, whereas ordinary crystallised silica has the sp. gr. 2.6, and silica of sp. gr. 2.3 has hitherto been observed only in the amorphous state.

On the preparation of crystallised silica in the dry way, see G. Rose (*Zeitschr. f. Chem.* [2] v. 646). On Graham's colloidal silica, see vol. v. pp. 241, 1088.

Hydrates (Merz, *J. pr. Chem.* xcix. 177).—Gelatinous silica obtained by decomposing gaseous silicon fluoride with water, continuously washed, with frequent pressure, dried, pulverised, and again washed, first with ammoniacal and then with pure water, retained, after six weeks' drying in the air at $20^\circ\text{--}25^\circ$, from 13.1 to 13.5 p. c. water, answering to the formula $2\text{SiO}^2 \cdot \text{H}^2\text{O}$; the amount of water was diminished by exposure over sulphuric acid, but was recovered on exposure to the air. After drying at 60° , or after prolonged desiccation over sulphuric acid, the

hydrate $3\text{SiO}_2 \cdot \text{H}_2\text{O}$ remained (containing 8.68 and 9.24 p. c. water; calc. 9.04 p. c.); at 80° – 100° the very unstable hydrate $4\text{SiO}_2 \cdot \text{H}_2\text{O}$ (containing 6.17 to 7.40 p. c. water; calc. 6.93 p. c.); after drying at 250° – 270° , the amount of water (3.29 to 3.59 p. c.) agreed with the formula $8\text{SiO}_2 \cdot \text{H}_2\text{O}$. Recently prepared silica retains smaller quantities of water at the several temperatures above cited (at 70° only about 6 p. c.; at 90° , 4.6 p. c.; at 100° , 4.3 p. c.; at 130° , 3.5 p. c.; at 160° , 3 p. c.); it appears therefore to undergo a gradual molecular alteration.

The hydrates, together with the monohydrate obtained by Graham, form the following series:

The third and fourth of these were previously obtained by Fuchs (v. 242). The hydrates $3\text{SiO}_2 \cdot 2\text{H}_2\text{O}$ and $2\text{SiO}_2 \cdot 3\text{H}_2\text{O}$, described by Ebelmen and Doyeri, do not appear to have been obtained by Merz. The hydrate obtained by the action of moist air on silicon tetrachloride has, according to Langlois (*Jahresb.* 1858, p. 140), the composition $9\text{SiO}_2 \cdot 4\text{H}_2\text{O}$.

Solubility in Ammonia.—According to Wittstein (*Jahresb.* 1866, p. 192), ammonia dissolves perceptible quantities of amorphous silica, not only in the gelatinous, but also in the dry and ignited state; even pulverised quartz is attacked by it. When a clear solution of water-glass supersaturated with hydrochloric acid is gradually mixed with ammonia, a strong flocculent turbidity is produced, which, however, disappears on addition of more ammonia, either in the cold or at a gentle heat. 100 pts. of aqueous ammonia containing 10 p. c. NH_3 dissolve, of:

Crystallised silica	0.017 pt.
Amorphous silica, ignited	0.38 „
Amorphous silica, as hydrate*	0.21 „
Amorphous silica, in the form of jelly.	0.71 „

The solutions prepared by contact of the silica with the aqueous ammonia in closed vessels for several days sometimes clarified but slowly; that obtained with the gelatinous acid was slightly opalescent. By prolonged exposure to the air they lost their alkaline reaction, and then contained 4 eq. silica to 1 eq. ammonia. This neutral solution when boiled and evaporated does not yield any deposit, although $\frac{1}{2}$ of the ammonia has been driven off, and only 1 eq. ammonia remains in the liquid to 80 eq. silica. After complete evaporation there remains an amorphous, laminar, horny, translucent residue, likewise containing 80 eq. silica to 1 eq. ammonia, and nearly insoluble in water.

Solubility in Acids.—Wittstein has likewise observed that hydrated silica, at the moment of separation (as when cast iron or steel is dissolved in an acid), is more abundantly dissolved by nitromuriatic acid (3 pts. hydrochloric acid of sp. gr. 1.13 to 1 pt. nitric acid of sp. gr. 1.33) than by hydrochloric acid (sp. gr. 1.13) (*Jahresb.* 1868, p. 207).

SILICATES. On the classification of silicates, see Wurtz (*Chem. Soc. J.* xv. 397; *Rép. Chim. pure*, ii. 449);—Weltzien (*Systematische Uebersicht der Silicate*, Giessen, 1861; *Jahresb.* 1864, p. 211);—Schiff (*Ann. Ch. Pharm. Suppl.* iv. 27; *Jahresb.* 1865, p. 194);—Frémy (*Compt. rend.* lxiv. 243; *Jahresb.* 1867, p. 202).

Cleve and A. E. Nordenskjöld (*J. pr. Chem.* c. 119; *Jahresb.* 1867, p. 980) designate a number of hydrated hygroscopic silicates, formed on the type of hisingerite, as *ferruginous colloidal silicates*, and represent them by the following formulae:

On the formation of natural silicates, and the alteration of the specific gravity of silicates by heat, see F. Mohr (*Kölnische Zeitung*, 1865, Nr. 156; *Jahrb. Min.* 1866, p. 181; *Jahresb.* 1866, p. 911), and C. W. Fuchs (*Jahrb. Min.* 1865, p. 576; *Jahresb.* 1865, p. 865).

Dauvrée (*Compt. rend.* lxiv. 339; *Jahresb.* 1867, p. 1010) has made experiments on

* Prepared from the hydrochloric acid solution by evaporation, washing, and drying, and containing a quantity of water answering to the formula $3\text{SiO}_2 \cdot 4\text{H}_2\text{O}$.

the action of water on various silicates under conditions analogous to those which occur in nature. The minerals were enclosed, together with an equal or a double weight of water, in cylindrical vessels of stone-ware or iron, which were made to rotate upon horizontal axes with a velocity equivalent to a rectilinear motion of 2500 metres per second. Felspar thus treated in a stone-ware cylinder with pure water was somewhat easily attacked, giving up to the water, potash, silica, alumina, and traces of sulphuric and hydrochloric acids; in the iron vessel, the silica was precipitated by the ferric hydrate formed by the oxidation of abraded iron. Three kilograms of felspar fragments rotated in the iron cylinder for 192 hours (corresponding to a distance of 460 kilometres), yielded 2720 grms. of mud, and the 5 litres of water took up 12.6 gm. potash: consequently from 2 to 3 p. c. of potash present in the dust had passed into solution. Water containing sodium chloride (3 p. c.) and carbonic acid water acted less quickly than pure water. Obsidian and leucitophyre were but very slightly attacked by pure water. With serpentine, obsidian, and angular lumps of felspar, the quantity of abraded powder amounted to 0.3 p. c.; with rounded lumps of felspar, to 0.2 p. c.; with flints, to 0.02 p. c. The state of the solid substance has some influence on its decomposibility; felspar which had been heated to whiteness and rapidly cooled was decomposed with increased facility. The abraded felspar powder exhibited considerable similarity to many clay-slates and lithomarges.

On the decomposition of silicates and other crystallised compounds by electro-capillary diffusion, see Becquerel (*Compt. rend.* lxxvii. 1081; *Zeitschr. f. Chem.* [2] v. 134).

For the decomposition of silicates in analysis, in cases in which the alkalis are to be determined, R. Hoffmann (*Zeitschr. anal. Chem.* vi. 366) recommends, instead of aqueous hydrofluoric acid, the use of ammonium fluoride with addition of sulphuric acid. The finely pulverised silicate is mixed with 3 or 4 pts. of pure ammonium fluoride, moistened in a platinum dish with sulphuric acid, and heated, with frequent addition of sulphuric acid, first over the water-bath, then over an open flame, till all the acid is expelled. The residue is dissolved in hydrochloric acid; the solution precipitated with ammonia and ammonium carbonate; then—after removing the sulphuric acid by barium chloride in case of magnesia being present—evaporated to dryness with addition of oxalic acid, and ignited. On heating the residue with water, the alkalis pass into solution.

According to F. Mohr (*Zeitschr. f. Chem.* v. 308), the decomposition of silicates by fluorides is greatly facilitated by previously submitting them in the pulverised state to intense ignition. They are then rapidly decomposed by gaseous hydrofluoric acid, without formation of the insoluble residue which so often occurs when unignited silicates are treated with hydrofluoric acid.

On the decomposition of silicates by hydrofluoric acid, see Maskelyne (*Chem. News*, xxi. 27; *Zeitschr. f. Chem.* [2] vi. 191).

Sodium metasilicate is obtained in monoclinic crystals containing $\text{Na}_2\text{SiO}_3 + 8\text{H}_2\text{O}$, by dissolving ignited silica in an equivalent quantity of caustic soda-ley, evaporating the decanted solution with as little contact of air as possible, till a number of small crystals of sodium carbonate fall down; then cooling the solution to -22° , and stirring it with a glass rod till it solidifies to a crystalline pulp; straining this mass to free it from the mother-liquor; dissolving it in a small quantity of distilled water; and leaving the solution to itself (Ammon, *Jahresb.* 1862, p. 138). According to Ordway (*Sül. Am. J.* [2] xl. 186), the same salt is easily prepared by dissolving the liquid layer obtained by precipitating a purified solution of soda water-glass (1 mol. Na_2O , 2.25 mol. SiO_2) with twice its volume of alcohol, in an equal weight of soda-ley of sp. gr. 1.32, and exposing the solution to a low temperature; the crystals which form in a few hours may be purified by recrystallisation from water. The salt melts at 45° to a syrup which does not resolidify; at a higher temperature it gives off its water, leaving a spongy mass, which is still easily soluble in water (Ammon). It has not been found possible to prepare a crystallised silicate of potassium or a crystallised double silicate of potassium and sodium by either of the processes above mentioned.

The metasilicates of the earth-metals may be prepared by precipitating a dilute solution of the sodium salt with a solution, mostly diluted, of an earth-metal salt. The *barium salt*, BaSiO_3 or $\text{BaO} \cdot \text{SiO}_2$, is not quite insoluble in hot water, perfectly soluble in dilute hydrochloric acid, and retains a somewhat considerable quantity of water even after drying at 100° . The *calcium salt*, CaSiO_3 or $\text{CaO} \cdot \text{SiO}_2$, is a white, very bulky, gelatinous precipitate, which also retains water with great obstinacy, and when left in contact with water for a long time, dissolves in it, apparently with partial

decomposition. The *strontium salt* is exactly similar in composition and properties. The *magnesium salt*, $3\text{MgSiO}_3 + 5\text{H}_2\text{O}$, is soluble in dilute acids, is not completely decomposed by hydrochloric acid after ignition, and fuses together when strongly ignited. When recently precipitated alumina is added to a moderately concentrated and boiling solution of caustic soda and sodium silicate, all the alumina dissolves in the first instance, but afterwards a white powder is deposited consisting of a *sodio-aluminic silicate*. The reaction appears to be as follows:

When a hot dilute solution of alum is precipitated with sodium silicate, a gelatinous precipitate is formed, whitish and very light when dry, consisting of a double silicate in which the oxygen of the silica is double that of the bases—that is to say, of a meta-silicate:

A similar experiment with excess of aluminium sulphate and sodium silicate also gave a metasilicate of aluminium. Results for the most part similar were obtained with silicate of potassium (Ammon).

Acid calcium silicate, $\text{CaO} \cdot 3\text{SiO}_2 + 2\text{H}_2\text{O}$ or $\text{CaSiO}_3 \cdot 2\text{SiO}_2 + 2\text{H}_2\text{O}$, is obtained on mixing calcium chloride with acid potassium silicate, $\text{K}_2\text{O} \cdot 3\text{SiO}_2$, as a gelatinous precipitate which gradually becomes crystalline under the liquid, and when dried at 100° has the composition above given; it does not harden when mixed, either in the air-dried or in the ignited state, with calcium hydrate, or a solution of that substance in sugar-water. *Acid magnesium silicate*, $\text{MgO} \cdot 2\text{SiO}_2 + 2\text{H}_2\text{O}$, is obtained in like manner as a gelatinous precipitate which does not become crystalline in contact with the liquid (Heldt, *J. pr. Chem.* xciv. 129, 157).

SILICIC CHLOROFORM. The silicohydric chloride (v. 268) which Wöhler a. Buff obtained in 1857 by passing hydrochloric acid gas over heated crystallised silicon, and to which Wöhler assigned the formula $\text{Si}^3\text{H}^1\text{Cl}^{10} = 3\text{SiCl}_2 \cdot 4\text{HCl}$, has been shown by Friedel a. Ladenburg (*Bull. Soc. Chim.* [2] vii. 322) to be a mixture separable by repeated fractional distillation into a portion boiling between 35° and 37° , and another boiling between 55° and 60° . The latter is silicic chloride, SiCl_4 . The former consists of silicic chloroform, SiHCl_3 , having a vapour-density = 4.64 (calc. 4.69). This compound possesses all the essential characters of the silicohydric chloride described by Wöhler a. Buff: its vapour mixed with air takes fire even by contact with a hot body. From the tetrachloride, which it resembles in appearance and in odour, it is immediately distinguished by its property of being decomposed by water, with evolution of hydrogen. Chlorine decomposes it at ordinary temperatures, forming silicic chloride and hydrochloric acid: $\text{SiHCl}_3 + \text{Cl}_2 = \text{SiCl}_4 + \text{HCl}$; bromine appears not to act on it below 100° . The white oxide produced in the decomposition of silicic chloroform by water, and regarded by Wöhler a. Buff (v. 274) as $3\text{SiO} \cdot 2\text{H}_2\text{O}$, afterwards by Wöhler as more probably consisting either of $\text{Si}^3\text{H}^1\text{O}^{10}$ or of $\text{Si}^3\text{H}^1\text{O}^9$, and by Geuther (*Jahresb.* 1865, p. 189) as $2\text{SiO} \cdot \text{HO}$ [$\text{Si} = 21$], is prepared by Friedel a. Ladenburg by slowly passing the vapour of pure silicic chloroform through a tube with a funnel-shaped termination into water at 0° , filtering quickly, washing the precipitate with ice-cold water, and drying it first over oil of vitriol, then at 150° . In this state it has the composition of silicic formanhydride, $\text{SiH}_2\text{O}_2 = (\text{SiOH})^2\text{O}$, analogous to the unknown formic anhydride $(\text{COH})^2\text{O}$. Its formation is represented by the equation:

(Friedel a. Ladenburg, *Bull. Soc. Chim.* [2] vii. 322).

SILICIC ETHERS. When chlorine is passed into well-cooled silicon-ethyl (v. 266), the liquid first turns yellow, then suddenly colourless, and gives off hydrochloric acid. If the product be distilled after some time, and the portion boiling below 160° again treated with chlorine, these operations being repeated several times, there is finally obtained a liquid boiling between 180° and 220° , and yielding by fractional distillation a small quantity of the compound $\text{SiC}^2\text{H}^4\text{Cl}$, which may be regarded either as *silicic monochlorotetraethyl*, derived from silicon-ethyl, $\text{Si}(\text{C}^2\text{H}^5)_4$, by substitution of 1 at. Cl for H, or as the *chloride of silicomonyl*, SiC^2H^3 , a radicle derived from nonyl, C^9H^{19} , by substitution of 1 at. silicon for carbon. The greater portion of the crude product distils between 190° and 195° , and has the composition of *silicic mono- and di-chlorotetraethyl* in equivalent proportions; but on continuing the distillation, the composition of the distillate approaches more nearly to that of the latter, and at 230° decomposition takes

place. If the portion of the product which distils between 180° and 200° be heated with potassium acetate and alcohol in sealed tubes to 130° – 140° , the dichlorinated compound is alone attacked; and on mixing the contents of the tube with water, and heating the oily liquid which separates with strong sulphuric acid, several ethereal compounds are dissolved—including *triethyl-silicic oxide*, $[\text{Si}(\text{C}^2\text{H}^5)^3]_2\text{O}$, formed from the silicic dichlorotetretrethyl—while *silicic monochlorotetretrethyl*, or *siliconyl chloride*, remains undissolved, and distils for the most part between 180° and 190° . On again heating this distillate to 180° with an alcoholic solution of potassium acetate, and mixing the contents of the tube with water, an oily product is obtained, which may be freed from undecomposed silicononyl chloride by treatment with strong sulphuric acid. The resulting solution poured into water deposits *silicononyl acetate*, $\text{SiC}^2\text{H}^{19}\text{O}$, as a liquid which boils between 208° and 214° , smells like acetic acid, and burns with a bright flame, giving off acetic acid. This liquid treated at 120° – 130° with a solution of potash in aqueous alcohol yields *silicononyl alcohol*, $\text{SiC}^2\text{H}^{19}\text{O}$, as a liquid insoluble in water, smelling like camphor, and boiling at 190° . Sodium dissolves in this alcohol, with evolution of hydrogen, forming a gelatinous substance which is decomposed by water, reproducing the original alcohol.

Triethylic Silicoformate, $\text{SiH}(\text{OC}^2\text{H}^5)^3$ or $\left\{ \begin{smallmatrix} (\text{SiH})^{\text{III}} \\ (\text{C}^2\text{H}^5)_3 \end{smallmatrix} \right\} \text{O}^3$, analogous to the tribasic formic ether discovered by Williamson a. Kay, is produced by dropping absolute alcohol into silicic chloroform contained in a long-necked flask. On gently heating the liquid after the reaction is over, and then distilling, the triethylic silicoformate is obtained, as a colourless, very hygroscopic liquid, boiling at 134° , and smelling like normal silicic ether: its vapour forms an explosive mixture with air. It is slowly attacked by water, quickly and with evolution of hydrogen by ammonia and potash. In contact with sodium it is resolved into tetrethylic silicate and silicic hydride, SiH^4 (p. 1021): $4\text{SiH}(\text{OC}^2\text{H}^5)^3 = 3\text{Si}(\text{OC}^2\text{H}^5)^4 + \text{SiH}^4$. The mode of action of the sodium has not been explained; it cannot be replaced by platinum-black (Friedel a. Ladenburg, *Bull. Soc. Chim.* [2] vii. 322).

Triethylic Silicochloroformate or *Ethylsilicic Monochlorhydrin*, $\text{SiCl}(\text{OC}^2\text{H}^5)^3$, discovered by Friedel a. Crafts (v. 264), is easily prepared by dropping 3 mol. absolute alcohol into 1 mol. silicic chloride, SiCl_4 , fractionating the product, and collecting apart the portion which passes over at about 156° . It is not acted upon by zinc-ethyl even at the boiling heat (Friedel a. Ladenburg).

Triethylic Silicopropionate or *Tribasic Silicopropionic ether*, $\text{SiC}^2\text{H}^3(\text{OC}^2\text{H}^5)^3 = \left\{ \begin{smallmatrix} (\text{SiC}^2\text{H}^3)^{\text{III}} \\ (\text{C}^2\text{H}^5)_3 \end{smallmatrix} \right\} \text{O}^3$, is produced by adding a few lumps of sodium to a mixture of 1 mol. zinc-ethyl and 2 mol. silicochloroformate, and applying a gentle heat, whereupon the action begins, and becomes very violent if not moderated, gas being copiously evolved, consisting chiefly of ethyl chloride, followed by ethyl and ethyl hydride (butane and ethane), while the sodium becomes covered with zinc-powder and gradually disappears. On distilling the mixture after the evolution of gas has ceased, and repeatedly fractionating, tribasic silicopropionic ether is obtained as the chief product, boiling between 159° and 162° , having a sp. gr. of 0.9207 at 0° , and vapour-density = 6.92 (calc. 6.65). It may be regarded as tribasic silicoformic ether, in which the hydrogen immediately connected with the silicon is replaced by ethyl, or as the triethylhydrin of a glycerin, in whose trivalent radicle, C^2H^3 , 1 at. carbon is replaced by silicon. It is an ethereal liquid of agreeable odour, resembling that of tetrethylic silicate; insoluble in water, miscible in all proportions with alcohol and ether. By moisture it is gradually resolved into alcohol and products boiling at higher temperatures, doubtless polysilicates analogous to those formed from normal silicic ether. It is not completely decomposed by ammonia. Like normal silicic ether, it is very stable, and is not oxidised by nitric acid till heated above 200° . Strong sulphuric acid decomposes it instantly. Heated with very strong potash-ley, it is quickly decomposed, with formation of two layers of liquid, both of which are dissolved by water, with separation of oil-drops. On neutralising the resulting solution with hydrochloric acid, or, better, on adding sal-ammoniac to the neutral liquid, a white flocculent precipitate separates resembling silica. This precipitate dried over sulphuric acid forms a white powder which blackens and burns when heated on platinum-foil. It dissolves in potash and is reprecipitated by hydrochloric acid. The slightly alkaline solution forms with silver nitrate a white or yellowish precipitate containing silver oxide and silicopropionic acid, $\text{C}^2\text{H}^3\cdot\text{SiO}^2\text{H}$. Tribasic silicopropionic ether is therefore decomposed by potash in the manner represented by the equation:

the decomposition being analogous to that of tribasic formic ether:

When triethyl silicoformate is treated in presence of sodium with 1 mol. (instead of $\frac{1}{3}$ mol.) zinc-ethyl, the reaction takes place in the manner above described, but the product boils at a lower temperature and contains more carbon. This body, which boils between 155° and 156° , consists of $\text{Si}(\text{C}^2\text{H}^3)^2(\text{OC}^2\text{H}^3)^2$, and appears to be produced by reduction of tribasic silicopropionic ether at the moment of its formation. The same compound would be formed by the action of zinc-ethyl and sodium on dichlorosilicic ether (Friedel a. Ladenburg (*Compt. rend.* lxi. 816; *Zeitschr. f. Chem.* [2] iv. 567; *Jahresb.* 1868, 427).

Trichlorosilicic oxide, $\text{O}\left\{\begin{smallmatrix} \text{SiCl}^3 \\ \text{SiCl}^3 \end{smallmatrix}\right.$, analogous to perchloromethyl ether, $(\text{CCl}^3)^2\text{O}^2$, is formed by passing the vapour of silicic chloride through an exhausted porcelain tube containing fragments of felspar, and heated nearly to the melting point of the latter. By repeating the same treatment several times with the more volatile portion of the condensed product, a considerable quantity of a mixture is at length obtained, which volatilises above 70° , and may be resolved by fractional distillation into silicic chloride and trichlorosilicic oxide, the latter passing over between 136° and 139° . The oxygen is derived from the felspar, as is shown by the corrosion of the fragments and the presence of solidified drops of alkali-metal chlorides. Trichlorosilicic oxide is also formed, together with phosphorus oxychloride, by passing silicic chloride over strongly heated phosphoric anhydride. Trichlorosilicic oxide is a colourless fuming liquid, having a vapour-density = 10.05 (calc. 9.86). It is decomposed by water like the tetrachloride, and is converted by absolute alcohol into disilico-hexethylic ether, $\text{O}\left\{\begin{smallmatrix} \text{Si}(\text{OC}^2\text{H}^3)^3 \\ \text{Si}(\text{OC}^2\text{H}^3)^3 \end{smallmatrix}\right.$, which may be separated from the product by fractional distillation, and boils at 235° - 237° . When 1 mol. trichlorosilicic oxide is heated to 180° in a sealed tube for 16 to 18 hours with 3 mol. zinc-ethyl, triethyl-silicic oxide is produced:

(Friedel a. Ladenburg, *Bull. Soc. Chim.* [2] ix. 358).

SILICIC HYDRIDE, SiH^4 , originally obtained mixed with hydrogen by the action of hydrochloric acid on magnesium silicide (Wöhler a. Buff, v. 273), may be prepared in the pure state by decomposition of triethyl silicoformate (p. 1020) in contact with sodium:

Silicic hydride thus obtained is a colourless gas, agreeing in all essential characters with that described by Wöhler a. Buff, but not spontaneously inflammable at ordinary pressure and temperature, but only when gently heated under reduced pressure, or when diluted with hydrogen. If a hot knife-blade be held near the bubbles of the gas as they rise over mercury, they take fire with explosion, and the mercury becomes sufficiently heated to set fire to the following bubble; in a eudiometer, also, the gas takes fire on admission of air, if the column of mercury is between 100° and 150° mm. high. Pure silicic hydride decomposed by potash yields 4 volumes of hydrogen, according to the equation:

(Friedel a. Ladenburg). Silicic hydride (impure prepared from magnesium silicide) is decomposed by bromine, forming a solid and a liquid compound, (SiBr^4 ?), the former crystallising in needles. With iodine it forms SiHI^3 and SiI^4 . It is also decomposed by the chlorides of sulphur, phosphorus, antimony, and tin (Mahn, *Zeitschr. f. Chem.* [2] v. 730).

SILICIC IODIDES. The **tettriiodide**, SiI^4 , is produced by passing iodine-vapour in a stream of carbon dioxide through a long porcelain tube nearly filled with silicon and heated to redness, and sublimes in the cooler part of the tube as a white crystalline mass. If the iodine is in excess, the product is mixed with free iodine, which may be removed by solution in carbon bisulphide (which easily dissolves the silicic iodide), and agitation of the solution with metallic mercury. Silicic iodide, SiI^4 , crystallises by sublimation, or by cooling or evaporation of its solution in carbon bisulphide, in colourless transparent regular octohedrons, which do not act upon polarised light; smaller quantities crystallise in dendritic forms. It melts at 120.5° to a yellowish

liquid, and resolidifies to a mass having a silky lustre and usually coloured red by separated iodine. It boils at about 200° , and distils without alteration in a stream of carbon dioxide. The vapour-density (determined at 360°) is 19.12 (calc. 18.56). The heated vapour burns in the air with a red flame and with abundant evolution of iodine. By water it is converted into silica and hydriodic acid; by absolute alcohol into silica, ethyl iodide, and hydriodic acid:

(Friedel, *Ann. Ch. Pharm.* cxlix, 96).

Tri-iodide. SiI^3 .—When silicon tetriiodide is heated nearly to its boiling point (290° – 300°) with finely divided silver, a white mass is obtained, which may be freed from unaltered tetriiodide by repeated treatment with small quantities of carbon bisulphide, and then dissolved, with aid of heat, in a large quantity of that liquid.

The solution on cooling yields the tri-iodide $\text{SiI}^3 = \begin{matrix} \text{SiI}^3 \\ | \\ \text{SiI}^3 \end{matrix}$ in beautiful colourless

hexagonal prisms or rhombohedrons, having a single axis of double refraction, fuming and changing into a white mass on exposure to the air. When treated with potash, it yields silica, hydriodic acid, and free hydrogen, in quantities corresponding to the equation:

Silicon tri-iodide cannot be distilled under either ordinary or reduced pressure. It may be partially sublimed, but decomposes for the most part into tetriiodide and an orange-red residue, insoluble in carbon bisulphide, benzol, chloroform, and silicon tetrachloride, and converted by water into a white or greyish substance which eliminates a large quantity of hydrogen from potash-solution, and has nearly the composition of the di-iodide, SiI^2 . The tri-iodide melts in a vacuum at about 250° , but appears to decompose partially at the same time. With ice-cold water the crystals of the tri-iodide decompose, without evolution of hydrogen, and are converted into a white mass, which after drying, first in a vacuum, and then at 100° , has the composition $\text{Si}^2\text{H}^2\text{O}^4 = \text{Si}^2 \left\{ \begin{matrix} (\text{OH})^2 \\ \text{O}^2 \end{matrix} \right\}$ or $\text{Si}^2\text{O}^2 \left\{ \begin{matrix} \text{H}^2 \\ \text{O}^2 \end{matrix} \right\}$, analogous to oxalic acid. This substance when heated, decomposes with incandescence and evolution of hydrogen, leaving nearly its own weight of silica. The tri-iodide appears to be converted by water, first into $\text{Si}^2(\text{OH})^4$, and then, by loss of $2\text{H}^2\text{O}$, in silico-oxalic acid, $\text{Si}^2\text{H}^2\text{O}^4$. Salts of this acid cannot be prepared, inasmuch as it is decomposed, with evolution of hydrogen, even by the weakest bases.

When the tri-iodide is mixed by small portions with zinc-ethyl and gently warmed, a white mass separates; and on distilling the liquid after the requisite quantity of the iodide has been added (2SiI^3 to $3(\text{C}^2\text{H}^5)^2\text{Zn}$), washing the distillate first with water, then repeatedly with strong sulphuric acid, and lastly with water again, then drying and submitting it to fractional distillation, silicon-tetrethyl passes over at 150° – 154° , and at 250° – 253° a liquid having the composition of silicon-triethyl, $\text{Si}^2(\text{C}^2\text{H}^5)^4$. This liquid has a faint odour, like that of silicon-tetrethyl, and burns with a luminous flame depositing silica. Vapour-density obs. = 8.5; calc. 7.96. The slight difference arises from the formation at 300° of a small quantity of a product soluble in concentrated sulphuric acid, doubtless the oxide $\text{Si}^2(\text{C}^2\text{H}^5)^4\text{O}$ (Friedel a. Ladenburg, *Compt. rend.* lxxviii, 920; *Zeitschr. f. Chem.* [2] v. 289).

In the compounds just described the two atoms of quadrivalent silicon are united into a sexvalent group, just like the two atoms of carbon in the ethyl-compounds; the tri-iodide, SiI^3 , for example, is analogous to C^2Cl^4 or C^2H^4 .

SILICIC IODOFORM. SiHI^3 , is formed in very small quantity by the action of hydriodic acid on silicon, somewhat more abundantly when the hydriodic acid gas is mixed with hydrogen. It then condenses in drops, together with the solid iodide, and may be separated from the latter, though not easily, by distillation. It is a colourless, strongly refracting liquid, of sp. gr. 3.362 at 0° , and 3.314 at 20° ; boils at about 220° . It is decomposed by water in the same way as silicic chloroform. The hydrosilicic iodide described by Wöhler a. Buff (v. 274) appears to have been a mixture of silicic iodide with a very small quantity of silicic iodoform (not more than 8 p. c. of the mixture) and free iodine. The red solution of this substance in carbon bisulphide is decolorised by agitation with metallic mercury, and after the evaporation of the solvent, leaves a yellowish liquid which solidifies to a crystalline mass and distils at 285° . It dissolves in potash with evolution of hydrogen, the quantity of which however is unimportant (0.036 p. c.), and much smaller than that which corresponds to the formula $\text{Si}^2\text{H}^2\text{I}^6$ (0.60 p. c.); the amount of silicon agrees with the formula SiI^4 (Friedel, *loc. cit.*).

SILICIC SULPHYDRATE (chlorinated). $\left. \begin{smallmatrix} \text{SiCl}^3 \\ \text{H} \end{smallmatrix} \right\} \text{S}$. *Silicic Mercaptan*.—

This compound, analogous to methyl-mercaptan, $\left. \begin{smallmatrix} \text{CH}^3 \\ \text{H} \end{smallmatrix} \right\} \text{S}$, is produced by passing a mixture of hydrogen sulphide and vapour of silicic chloride through a red-hot tube:

It is a colourless liquid, boiling at 196° , smelling of hydrogen sulphide and silicic chloride, and decomposed by moist air, with formation of silica, hydrochloric acid, and sulphur. With absolute alcohol it forms normal silicic ether, $\text{Si}(\text{OC}^2\text{H}^5)^4$, the compound $\text{Si}(\text{OC}^2\text{H}^5)^3\text{HS}$ being apparently also formed as an intermediate product. Dry bromine decomposes silicic mercaptan, with rapid evolution of hydrobromic acid and formation of silicic chlorobromide, SiCl^3Br :

The chlorobromide, separated by distillation from the bromine sulphide, is a colourless liquid, which fumes in the air, boils at 80° , and has a vapour-density = 7.25 (calc. 7.42). With water it is resolved into silica, hydrochloric acid, and hydrobromic acid. Silicic chlorobromide is likewise obtained by heating silicic chloroform to 100° for some time with bromine, and submitting the product to fractional distillation (Friedel & Ladenburg, *Bull. Soc. Chim.* [2] vii. 472).

SILICOFLUORIDES. The specific gravity of potassium silicofluoride is 2.6649–2.6655 at 17.5° ; of the sodium salt, 2.7517 at 17.5° ; of the barium salt, 4.2741 at 21° , all referred to an equal volume of water at 15° as unity (Stolba, *J. pr. Chem.* xcvi. 503).

Potassium Silicofluoride, recently precipitated in the cold, collected on a filter, and left to itself for 24 hours, retains from 63 to 65 p. c. water; when precipitated from a hot solution, it retains 45 to 46 p. c. The gelatinous precipitate appears crystalline under the microscope, especially if moistened with a little alcohol. It is less soluble in saline solutions than in pure water: 1 pt. of the salt requires for solution 833 pts. water at 17.5° ; 24,066 pts. of a solution of potassium sulphate (of 9.92 p. c.) at 17° ; 125,000 of an 18.4 p. c. solution of potassium nitrate at 15° ; 1735 pts. of an 8.8 p. c. solution of the same salt at 100° . Aqueous sal-ammoniac of 26.3 p. c. dissolves it more easily than a 5 p. c. solution of the same salt. Acids dissolve potassium silicofluoride more easily than water, but decompose it at the same time, usually with emission of vapours of silicon fluoride. In hydrochloric acid, however, the salt dissolves without formation of visible decomposition-products, and more abundantly in proportion as the acid is stronger. When potassium silicofluoride is ignited with 1 to 2 pts. of sal-ammoniac, ammonium silicofluoride is given off, and potassium chloride remains behind. When the potassium salt is boiled with carbonate of magnesium or calcium, in presence of water, fluoride of magnesium or calcium is formed, but the decomposition is never complete (Stolba, *J. pr. Chem.* ciii. 396; *Zeitschr. f. Chem.* [2] iv. 576).

Cæsium Silicofluoride, $2\text{CsF} \cdot \text{SiF}^4$, is prepared by precipitating cæsium chloride with cupric silicofluoride, and washing the precipitate on a filter till all the copper salts are removed; it forms anhydrous crystals. When precipitated by alcohol it is not distinctly crystalline, but from a hot solution it separates in shining octohedrons truncated by cubic faces. By spontaneous evaporation, cubes with truncated summits are obtained. Sp. gr. 3.3756 at 17° . One part of the salt dissolves in 166 pts. water at 17° , and in a much smaller quantity of hot water, but it is insoluble in alcohol. Ignited with sal-ammoniac it leaves pure cæsium chloride. It is easily and completely decomposed by lime-water (Stolba, *J. pr. Chem.* ciii. 410).

Rubidium Silicofluoride, $2\text{RbF} \cdot \text{SiF}^4$, is precipitated from hot solutions as a distinctly crystalline powder, appearing under the microscope to consist of transparent cubes modified with octohedral and dodecahedral faces; the precipitate formed in the cold is less crystalline. Sp. gr. 3.3383 at 20° referred to water at the same temperature. 1 pt. of the salt dissolves in 614 pts. water at 20° , in 738 pts. at the boiling heat. The aqueous solution has an acid taste and reaction; a solution saturated at 20° has a sp. gr. of 1.0013. The salt is more soluble in acids than in water; insoluble in alcohol; reacts with alkalis like the potassium and sodium salts (Stolba, *J. pr. Chem.* cii. 1).

Cupric Silicofluoride, $\text{CuF}^2 \cdot \text{SiF}^4$, may be prepared by dissolving cupric carbonate in dilute silicofluoric acid, or by boiling barium silicofluoride with the solution of an equivalent quantity of cupric sulphate (adding a small quantity of the barium salt towards the end of the process till the sulphuric reaction disappears), and evaporating in a vacuum at 10° to 22° . It forms crystals belonging to the hexagonal

system and consisting of $2(\text{CuF}^2 \cdot \text{SiF}^4) + 13\text{H}^2\text{O}$. Sp. gr. = 2.1576 at 19° referred to water at the same temperature. The crystals deliquesce in moist, effloresce in dry air, and decompose at 100° , giving off silicon fluoride. The salt is very soluble in water, 1 pt. of it dissolving in 0.428 pt. water at 17° (sp. gr. of the solution 1.6241); 1 pt. of it dissolves also at 20° in 17.7 pts. of 62 p. c. alcohol, in 150 pts. of 85 p. c. alcohol, and in 617 pts. alcohol of 92 p. c. From the saturated solution in weak spirit there separates, on heating, or on addition of an excess of the salt, or on addition of stronger alcohol, a heavy blue liquid not miscible with the solution, and consisting of cupric silicofluoride, water, and alcohol, in variable proportions; a larger addition of strong alcohol throws down a light blue powder containing less water (according to one experiment, $2\text{CuSiF}^6 + 11\text{H}^2\text{O}$). Cupric silicofluoride, on account of its easy solubility in water and weak spirit, and its property of not corroding glass in aqueous solution, may be conveniently used as a reagent, especially for precipitating alkalis from solutions not containing sulphuric acid (Stolba, *Zeitschr. f. Chem.* [2] iv. 95).

SILICO-FORMANHYDRIDE. See page 1019.

SILICO-OXALIC ACID. See page 1022.

SILICOPROPIONIC ACID. See page 1020.

SILK (Cramer, *Untersuchung der Seide und des thierischen Schleims*, Inaug. Diss. Zürich, 1863; *J. pr. Chem.* xvi. 76; *Jahresb.* 1864, p. 628; 1865, p. 653).—When silk is exhausted with water in a Papin's digester six times successively for two or three hours each, under a pressure of three atmospheres (at 133°), and the pale yellow shining residue is freed from colouring matter by treatment with strong alcohol, and from a trace of fatty matter by ether, the undissolved portion, amounting to 66 p. c. of the silk, consists of fibroin, $\text{C}^{15}\text{H}^{22}\text{N}^2\text{O}^6$, having the appearance of cleansed silk, and easily torn (but not pulverisable). Fibroin boiled for some time with dilute sulphuric acid yields glycocine, together with leucine and tyrosine, the amount of the two former being about five times as great as that of the tyrosine.

Sericin or *Silk-gelatin* is obtained by boiling silk with water for about three hours, precipitating the expressed liquid with basic lead acetate, and decomposing the washed precipitate suspended in hot water with hydrogen sulphide. The liquid separated therefrom and somewhat concentrated, is first mixed with a quantity of alcohol just sufficient to produce a permanent precipitate, and the sericin is then precipitated from the clear filtrate by further addition of alcohol. After boiling with alcohol and ether, drying, and pulverisation, it forms a colourless, scentless, and tasteless powder, which swells up strongly in water, and dissolves in hot water more easily than ordinary gelatin. A solution containing less than 1 p. c. still coagulates on cooling to a consistent jelly, which, however, loses this property by prolonged boiling, as well as by addition of acetic acid, potash, or soda. Tannic acid produces in the solution a white thick flocculent precipitate; ferrocyanide and ferricyanide of potassium do not form any precipitate in the solution acidulated with acetic acid; aluminium sulphate and the salts of most of the heavy metals form precipitates which partly dissolve when heated, or in an excess of the precipitant.

The analysis of sericin leads to the formula $\text{C}^{15}\text{H}^{22}\text{NO}^6$, differing from that of fibroin by addition of O and H^2O . The formation of sericin from fibroin by oxidation is in accordance with the fact that fibroin, after prolonged exposure to the air, becomes attackable by water; but the products of decomposition by sulphuric acid do not agree with this supposition. Sericin, in fact, when boiled for some time with a mixture of 1 vol. sulphuric acid and 4 vol. water, yields no glycocine, and only a small quantity of leucine, but, on the other hand, about 6 p. c. tyrosine and 10 p. c. of a body called serine, closely related to alanine.

Serine.—To prepare this substance, silk is moistened in the bag till its surface is sufficiently softened—an operation often performed in dye-works for the purpose of cleansing—and then immersed for a short time in boiling water. To obtain a sufficiently concentrated solution, several portions of silk are treated with the same quantity of water, and the liquid is evaporated till it contains from 7 to 8 p. c. sericin. It is then mixed with $\frac{1}{4}$ vol. sulphuric acid, boiled for 24 hours in a flask with upright condenser, and supersaturated with lime. The filtrate neutralised from time to time with sulphuric acid deposits on evaporation, first tyrosine and gypsum, and then serine in groups of crystals; finally a small portion of leucine crystallises from the mother-liquor. The serine, after being pressed, is dissolved for further purification in 40 pts. of cold water, and the solution filtered from tyrosine is mixed with a few drops of ammonia and ammonium carbonate to precipitate a small quantity of lime, and evaporated to the crystallising point. The last residue of

colouring matter is removed by mixing the solution with a few drops of basic lead acetate, and treating the filtrate with sulphuric acid.

Serine, $C^3H^2NO^3$, forms colourless monoclinic crystals mostly aggregated in crusts or glandular masses, hard, brittle, soluble in 32 pts. water at 10° , in 2.4 pts. at 20° , more soluble in hot water, insoluble in alcohol and ether. The aqueous solution has a faint sweetish taste, and is neutral to vegetable colours. *Copper-serine*, $(C^3H^2NO^3)^2Cu$, is formed on boiling a solution of serine with cupric oxide, and separates from the deep blue solution in crystals resembling copper-alanine. The silver compound is easily decomposable, and the barium compound, obtained by boiling serine in barium carbonate, cannot be obtained of constant composition. In dilute mineral acids serine dissolves much more easily than in water, and without neutralising them. From solution in strong hydrochloric acid, *serine hydrochloride*, $C^3H^2NO^3 \cdot HCl$, crystallises by spontaneous evaporation over lime and oil of vitriol, in concentric groups of colourless needles, easily soluble in water, sparingly in alcohol. The *nitrate*, $C^3H^2NO^3 \cdot NHO^3$, is obtained from the hydrochloride by decomposition with silver nitrate, and crystallises by evaporation over lime and oil of vitriol, in easily soluble microscopic needles. The sulphate is also crystallisable.

The relations of serine to alanine and cystine may be represented by the following formulæ:

The triatomic radicle C^3H^2O is the radicle of glyceric acid, $(C^3H^2O)^{\sim}(OH)^3$, which acid is in fact produced by treating the aqueous solution of serine with nitrous acid (Cramer).

Detection of other Fibres in Silk-fabrics.—According to Spiller (*Chem. News*, xxii. 169), the best reagent for this purpose is concentrated hydrochloric acid, which dissolves silk immediately and completely, without appreciably affecting any of the other fibres (wool, cotton, linen, jute, &c.) with which the silk may be interwoven. The silk having been thus dissolved, the residual fibres may be washed and examined by the methods given in the Dictionary under the heads CELLULOSE, COTTON, and WOOL. The different varieties of cellulose (cotton, flax, &c.) are best distinguished by their microscopic characters.

The mucilaginous solution of silk in hydrochloric acid forms with excess of ammonia a clear liquid which promises to be of use in photography, as when evaporated it leaves a brown saline residue, which when mixed with aqueous silver nitrate, yields silver chloride in a peculiar flocculent form, much more easily affected by light than the chloride in its ordinary state.

SILKWORM. On the nutrition of the silkworm, see Pélégot (*Bull. Soc. Chim.* [2] vi. 83).

SILVER. The most recent determinations by Stas of the atomic weight of this metal give as the mean value, 107.929; former determinations by the same chemist (1860) gave 107.931; and those of Marignac (i. 905) give 107.928. The atomic weight of silver may therefore be regarded as finally established and = 107.93 (*Recherches sur les Lois des Proportions chimiques, &c.*; *Jahresb.* 1867, p. 16).

Pure silver for these determinations was obtained: *a.* By reduction of purified silver chloride with potassium hydrate and milk-sugar (Levol's process), both freed from every trace of metallic impurity.—*b.* By a new method which, as regards facility and rapidity of operation and the purity of the product, is preferable to all others, and depends on the complete reduction of silver from ammoniacal solutions by ammoniacal cuprous sulphite, or by a mixture of ammonium sulphite with an ammoniacal cupric salt (alkaline sulphites without copper salts precipitate only half the silver, even at the boiling heat). At ordinary temperatures the reduction takes place slowly, the precipitated metal being black, blue, or grey according to the dilution of the liquid; but above 60° the reduction is almost instantaneous, and attended with precipitation of grey or white metal, not a trace of silver remaining in solution so long as the liquid does not turn blue. The process is conducted as follows: Silver coin is dissolved in dilute nitric acid; the solution is evaporated to dryness; the saline mass fused to decompose platonic nitrate,* then dissolved in ammoniacal-water; and the blue solution, clarified by long standing and filtration, is diluted to 50 times its amount of silver. A determination is then made of the quantity of this solution which is decolorised

* French silver coin was found by Stas to contain small quantities of iron and nickel, and traces of cobalt, platinum, and gold.

by a known volume of neutral ammonium sulphite at the boiling heat; the two liquids are mixed in the required proportions; the mixture is left at rest for 48 hours in a vessel closed air-tight, whereupon about a third part of the silver separates as a crystalline deposit; and the decanted dark blue solution is heated for some time to 60° – 70° , whereby, if a sufficient excess of ammonium sulphite is present, it is completely decolorised (unless the silver contains cobalt or nickel, in which case the liquid remains red or pale green). The precipitated silver, after being washed, is digested with concentrated ammonia (a small quantity of silver then passing into solution, and remaining on evaporation as a black specular of silver nitride), then washed and dried. To obtain it in compact form it is fused with 5 p. c. ignited borax mixed with $\frac{1}{2}$ sodium nitrate, and poured into moulds lined with a paste of ignited and unignited kaolin. The cooled bars are then cleaned with sand, ignited with pure potash (to remove the kaolin), and washed. If they have to be cut into smaller pieces with a steel chisel, the pieces must be again digested with pure strong nitric acid, and washed with ammoniacal and pure water.

Silver thus prepared, if the solution has been diluted to the degree above directed, is free from all but mere traces of volatile or oxidisable impurities. Exposed to the flame of the coal-gas and oxygen blowpipe in a crucible of burnt marble, it melts without becoming spotted; boils briskly at a higher temperature, giving out a pale blue flame (or purple from admixture of strontium, calcium, or lithium vapour from the substance of the crucible), colouring the burnt lime deep yellow, and finally volatilising without a trace of residuum.

Equally pure silver may be obtained, according to Stas, by Millon a. Commaillie's process of reduction with an ammoniacal solution of cuprous chloride (*Jahresb.* 1863, p. 283), provided this solution is free from iron. But a solution prepared with commercial copper always contains ferrous oxide, and therefore yields a silver precipitate containing ferric oxide, from which the iron cannot be separated, by any simple process.

Gräber (*Zeitschr. anal. Chem.* viii. 64) prepares pure silver by reducing an ammoniacal solution of the chloride with excess of zinc, digesting the washed precipitate with strong hydrochloric acid, washing it with water, then with aqueous ammonia, and then again with water. Pure silver may be separated in this manner from ammoniacal solutions containing copper, provided the quantity of zinc present is less than sufficient to reduce all the silver.

When cupriferosus silver is distilled as above in a kind of retort made of two pieces of burnt marble fitted one upon the other, part of the copper distils with the silver, and argentiferous copper remains in the retort, the copper for the most part as oxide. Lead is volatilised or oxidised before the silver.

Distilled silver is dazzling white, of sp. gr. 10.575, and softer than fused silver, by which it is scratched. Perfectly pure silver in very thin layers appears bluish-green by transmitted light, in somewhat thicker layers yellow to yellow-brown. Such deposits are obtained by dissolving silver in a hot solution of potassium cyanide, and when the liquid has cooled to 60° – 70° , dipping into it a glass tube heated to a somewhat higher temperature. In a tube thus lined with a very thin film of silver, a mixture of chlorine and hydrogen detonates instantly in sunshine; if the coating is thicker, the combination takes place in the course of a few hours without explosion (*Christomanos, Zeitschr. f. Chem.* [2] v. 310).

Foucault (*Compt. rend.* lxiii. 413) also found that thin silver specula transmit light with bluish colour (the translucency being a property of the silver and not dependent on porosity), and that therefore plane glasses or lenses silvered on one side might be used in optical instruments for diminishing the intensity of light.

Soulé (*Bull. Soc. Chim.* [2] viii. 136) describes a process now used in the United States for extracting gold and silver from their ores, which consists in forcing the finely pulverised and moistened ore (pyriteferous or quartzose) through melted lead by atmospheric pressure. The gold and silver, as well as the metallic oxides and sulphides, are taken up by the lead, while the exhausted ore rises to the surface, and is removed by a peculiar arrangement. The lead when sufficiently charged with gold or silver is expelled.

W. G. Blagden (*Mechanic's Magazine*, Sept. 1867, p. 220; *Jahresb.* 1867, p. 887) describes a method of desilvering lead by means of zinc and the electric current. The previously refined metal is heated to 450° in a pan like those used in Pattinson's process, about $\frac{1}{2}$ p. c. zinc is added, and as soon as it is completely dissolved, an electric current is passed into the bath by means of copper wires for 10 to 30 minutes. The zinc holding the silver in solution then rises to the surface, and may be removed as a solid crust when the bath has cooled to about 450° . For satisfactory desilverisation (down to $\frac{1}{500}$ p. c.) the operation must be repeated several times.

On the action of light on *chloride, bromide, and iodide of silver*, see Poitevin, *Bull. Soc. Chim.* [2] v. 155;—Kaiser, *Jahresb.* 1865, p. 279;—Carey Lea, *Sill. Am. J.* [2] xxxix. 74; xl. 109; xlii. 198; *Jahresb.* 1865, pp. 279, 282; 1866, p. 262;—H. Vogel, *Pogg. Ann.* cxv. 329;—W. Reissig, *J. pr. Chem.* xcv. 405;—Schultz-Sellack, *Deut. chem. Ges. Ber.* iv. 210; *Chem. Soc. J.* [2] ix. 302. According to Lea, pure silver iodide is not reduced by light, the reduction taking place only in presence of silver nitrate or organic bodies.

Silver Fluoride. AgF.—This compound has been carefully examined by Gore (*Phil. Trans.* 1870, 227; *Proc. Roy. Soc.* xix. 235). It was prepared by dissolving pure silver carbonate in hydrofluoric acid and evaporating in a platinum dish, but, unless peculiar precautions are taken, it generally contains a little metallic silver and traces of water and hydrofluoric acid. It is usually obtained in yellow earthy lumps, but when completely dehydrated by fusion, it forms a black horny mass, having a silvery lustre on the surface, arising from minute particles of metallic silver. It is extremely deliquescent; 1 pt. of it dissolves in 0.55 pts. water at 15.5°, heat being evolved in the dissolution, and a strongly alkaline liquid being formed. The saturated solution has a sp. gr. of 2.61 at 15.5°, exhibits supersaturation on cooling, and solidifies, with rise of temperature, when a platinum plate is dipped into it. Crystals of a hydrated salt may be obtained from the solution, but the rest of the salt separates at the same time in the anhydrous and amorphous state. The dry salt is not decomposed by light. It melts below a visible red heat, forming a strongly lustrous, mobile, pitch-black liquid. It is not decomposed by heat alone, but in the fused or semifused state it is quickly decomposed by the moisture of the air, with separation of metallic silver; dry air does not affect it. Brought in contact in the fused state with platinum poles, it conducts electricity like a metal, without visible evolution of gas or corrosion of the positive pole; a silver pole is quickly dissolved, and a carbon pole gradually attacked. The aqueous solution yields by electrolysis, silver crystals at the negative, and silver peroxide at the positive pole. Hydrogen does not affect the dry salt in sunshine, but decomposes it gradually at a commencing red heat, with separation of metallic silver. The dry salt and the aqueous solution are not decomposed by oxygen or by nitrogen; neither do the oxides of nitrogen act on the fused salt. Ammonia gas is quickly absorbed by the dry and by the fused salt, in the latter case with separation of metallic silver; the concentrated solution is also decomposed by strong aqueous ammonia. When vapour of hydrofluoric acid is passed over the perfectly dry and previously fused salt, at a temperature of 13°, an acid fluoride is formed, which however decomposes at a slightly higher temperature.

When silver fluoride is heated in chlorine gas, in vessels constructed partly of glass, partly of platinum, the glass is more or less attacked, the chlorine unites with the platinum and the silver fluoride, forming a double salt, $4\text{AgCl} \cdot \text{PtF}_4$, and a vacuum is produced. Similar results are obtained in vessels of platinum alone or of gold. In vessels constructed partly of purified graphite a compound of fluorine and carbon is formed. Bromine and iodine act upon silver fluoride in a similar manner; iodine however does not form a double salt analogous to the chlorine-compound above mentioned. An aqueous solution of silver fluoride agitated with chlorine becomes hot and gives off oxygen:

Dry hydrochloric acid gas completely decomposes silver fluoride in the melted state, but only acts upon it superficially at 60° F. A saturated aqueous solution of silver fluoride is not precipitated by chloric acid.

Silver Oxides. *Argentous Oxide*, Ag_2O , is produced by the action of hydrogen dioxide on metallic silver (and therefore also in the decomposition of argentic oxide by excess of hydrogen dioxide). A bright silver plate immersed in a perfectly neutral solution of hydrogen dioxide becomes covered with bubbles of oxygen and coated with a greyish-white film, while part of the silver is converted by addition into hydrated argentous oxide, according to the equation $2\text{Ag}^2 + \text{H}_2\text{O}_2 = 2\text{HAg}^2\text{O}$, and dissolves in the liquid; a small quantity of a grey-black precipitate is likewise deposited. The solution of argentous hydrate when exposed to the air acquires the colour of cobaltous salts, and becomes slightly clouded by separation of finely divided silver. With potash it forms a brown-black precipitate; with hydrochloric acid a precipitate of silver chloride and metallic silver: $2\text{HAg}^2\text{O} + 2\text{HCl} = 2\text{H}^2\text{O} + 2\text{AgCl} + \text{Ag}^2$. When evaporated it leaves a residue which appears crystalline under the microscope, and when treated with water gives up argentic hydrate and deposits metallic silver in transparent, red, microscopic crystals, according to the equation $2\text{HAg}^2\text{O} = 2\text{HAgO} + \text{Ag}^2$;

the solution of argentic hydrate thus obtained has a slight alkaline reaction, and gives with hydrochloric acid a precipitate of silver chloride (Weltzien, *Ann. Ch. Pharm.* cxlii. 105).

On the preparation of silver peroxide by electrolysis of an aqueous solution of the nitrate, see Böttger, *Zeitschr. f. Chem.* [2] vi. 82.

Decomposition of Organic Silver-salts by Water.—When silver malate is boiled with water till only traces of silver remain in solution, the liquid freed from these traces yields on evaporation nothing but malic acid. The tartrate similarly treated yields only tartaric acid; the vapours given off during the boiling of this salt have an acid reaction, and when neutralised with baryta-water yield barium-carbonate, together with small quantities of a barium salt which crystallises in acuminate needles (Kämmerer, *Ann. Ch. Pharm.* cxlviii. 237).

SINCALINE. From experiments by Claus A. Keesé (*J. pr. Chem.* cii. 24; *Jahresb.* 1867, p. 494), this base appears to be identical with neurine or choline.

SITESIN. The name applied by Commaille (*J. Pharm.* [4] iv. 108) to the casein of gluten.

SITOSIN. Commaille's name for the albumin of wheat-flour.

SODA. For the continuation of Kolb's researches on the soda-manufacture and the composition of soda-waste, see *Ann. Ch. Phys.* [4] viii. 135; x. 106; *Bull. Soc. Chim.* [2] vii. 370; *Jahresb.* 1866, p. 850; *Chem. News*, xiii. 162; xiv. 16, 40, 53. See also Petersen, *Bull. Soc. Chim.* [2] viii. 35; *Jahresb.* 1866, p. 853;—Weldon, *Chem. News*, xiv. 41;—Scheurer-Kestner, *Ann. Ch. Phys.* [4] xi. 220; *Bull. Soc. Chim.* [2] vii. 217; *Jahresb.* 1867, p. 904;—Hargreaves, *Chem. News*, xv. 219, 232; *Jahresb.* 1868, p. 931;—Wright, *ibid.* xvi. 17; *Chem. Soc. J.* [2] v. 407;—Brisse, *Bull. Soc. Chim.* [2] vi. 100, 134;—Kessler, *ibid.* 299; *Jahresb.* 1867, p. 907;—Schlösing A. Rolland, *Ann. Ch. Phys.* [4] xiv. 5;—Ungerer, *Dingl. pol. J.* clxxxviii. 140; *Bull. Soc. Chim.* [2] x. 160; *Jahresb.* 1868, p. 932.

SODIUM. This metal, together with the rest of the alkali-metals, has hitherto been regarded as monatomic or univalent. Wanklyn, however, from considerations relating to the composition and reactions of sodium-ethylate and other organic sodium-compounds, concludes that it is in most cases trivalent, sometimes also quinquivalent or septivalent, and possibly capable of exhibiting still higher degrees of combining capacity.

Crystallised sodium ethylate, or sodium alcohol, obtained by the action of sodium on absolute alcohol, has the composition $C^2H^4NaO.3C^2H^4O$, and when heated to 200° for some time gives off 3 mol. alcohol and leaves a white amorphous residue consisting of absolute sodium ethylate, C^2H^4NaO , or ethylene-sodium hydrate, C^2H^4NaOH (p. 593). To these two compounds Wanklyn assigns the following formulæ:

Ethylene-sodium hydrate is capable of uniting directly with hydrogen chloride, hydrogen sulphide, and acetyl chloride, forming compounds represented by the formulæ:

With ethyl acetate it forms ethylene-sodium acetate and alcohol:

Corresponding compounds containing the radicles valeryl and benzoyl are obtained in like manner. Sodium amylate or amylene-sodium hydrate, obtained by the action of sodium on amyl alcohol, likewise yields similar salts, e.g. the valerate

$$\text{Na}''' \left\{ \begin{array}{c} C^5H^{10} \\ OC^3H^7O \end{array} \right.$$

All these salts when treated with water yield ethylic or amylie alcohol, and an acetate, valerate, &c.: *e.g.*,

The preceding compounds might of course be represented by formulæ containing univalent sodium: *e.g.*,

But Wanklyn suggests that if sodium alcohol really had this constitution, that is to say, if it consisted of ethyl alcohol in which an atom of hydrogen in the ethyl-radicle was replaced by sodium, it should admit of the replacement of its sodium in that radicle by ethyl (*e.g.* when treated with ethyl iodide), and yield hydrate of ethylated ethyl, that is to say hydrate of butyl, or butylic alcohol. In like manner ethylene-sodium acetate, if it consisted of sodinated ethyl acetate, $\text{C}^2\text{H}^4\text{Na} \cdot \text{OC}^2\text{H}^3\text{O}$, should be converted by similar treatment into ethylated ethyl acetate or butyl acetate. But neither of these transformations is observed to take place. The acetate treated with ethyl iodide undergoes, in fact, a more complicated decomposition, yielding sodium iodide, alcohol, and acetylinated ethyl caproate; thus:

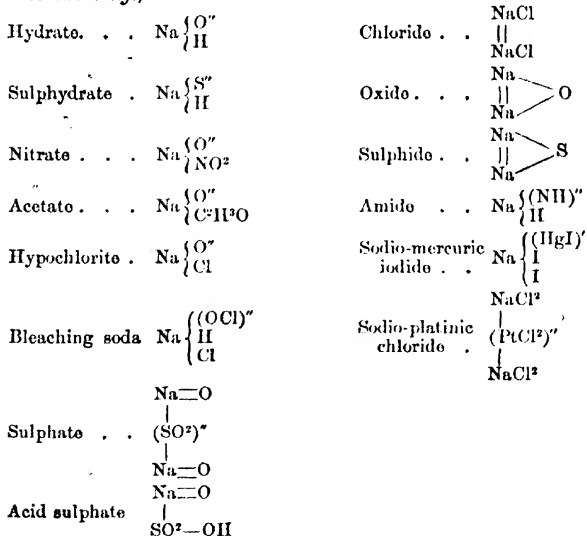

The trivalent character of sodium is further exhibited in sodium-triacetyl, $\text{Na}^{\text{'''}}(\text{C}^2\text{H}^3\text{O})^3$, produced, together with ethylene-sodium acetate, by the action of sodium on ethyl acetate (p. 15):

and in the double compound of sodium-ethyl and zinc-ethyl, $\text{Na}^{\text{'''}} \left\{ \begin{array}{c} (\text{ZnC}^2\text{H}^3)^{\text{'}} \\ \text{C}^2\text{H}^3 \end{array} \right.$.

The inorganic compounds of sodium may also be represented by formulæ containing trivalent sodium: *e.g.*,

This list might be indefinitely extended, so as to include a host of double chlorides, bromides, and iodides, which, on the usual hypothesis of the monad character of

sodium, are regarded as 'molecular compounds,' that is to say, as compounds whose structure we are not yet able to explain.

Precisely similar views may be taken of the constitution of the compounds of potassium and of the other alkali-metals. For further details, see *Ann. Ch. Pharm.* cli. 200; *Chem. News*, xx. 293, 313; xxi. 97.

Metallic sodium is not acted on by chlorine gas, either when it has been previously fused, or when agitated in the fused state with the gas (Wanklyn, *Chem. News*, xx. 271).

SODIUM-AMALGAM. See AMALGAMS, under MERCURY (p. 816).

SOLANINE. According to Kletzensky (*Zeitschr. f. Chem.* [2] ii. 127), this base has the composition $C^{12}H^{19}NO^2$, and in contact with sodium-amalgam is resolved into nicotine and butyric acid; it likewise yields nicotine when fermented with putrid cheese, sugar, and chalk.

SOMBRERITE. S. Houghton (*Phil. Mag.* [4] xxxii. 220) found in this mineral:

SiO ²	P ² O ⁵ Ca ²	CO ² Ca	KCl	CaF ²	H ² O
0.08	89.64	5.0	2.81	0.10	0.60 = 98.23

SPARTALITE. A specimen of this mineral from Sterling, Sussex County, New Jersey, analysed by C. U. Shepard (*Sill. Am. J.* [2] xxxix. 174), gave 13.79 p. c. MnO, 43.66 CaO, and 42.01 CO², agreeing with the formula ($\frac{1}{2}$ MnO, $\frac{1}{2}$ CaO).CO². Sp. gr. 2.811. To avoid confusion with the red zinc-ore called *spartalite* (v. 366), Shepard proposes to designate this calcio-manganous carbonate as *calcimangite*.

SPECTRAL ANALYSIS. *Applications to Terrestrial Chemistry.*—The only exception to the general fact that incandescent solids emit light of every degree of refrangibility has been observed by Bunsen (*Ann. Ch. Pharm.* cxxxvii. 1) in the case of glowing erbia, which gives a broken spectrum in which the bright lines are intense enough to serve as a means of detecting this rare earth. This singular phenomenon does not however constitute an exception to the law of exchanges; for Bunsen has shown that the bands of maximum intensity in the emission spectrum coincide exactly in position with the bands of greatest darkness in the absorption spectrum. A similar inversion of the didymium bands has also been observed by Bunsen. The same observer has published some interesting facts respecting the absorption spectrum of the erbium and didymium compounds when examined by polarised light (*Phil. Mag.* [1866] xxxii. 177). From these experiments it appears that the absorption-bands vary slightly, (1) according to the chemical nature of the particular salts of these metals employed, and (2) according as the ordinary or the extraordinary ray is allowed to pass through the crystal. A variation in these absorption-bands is also noticed according to the direction which the ray is passed through the crystal of sulphate, and again a difference is perceived in the nature of the absorption-band thus produced and those caused by absorption in a solution of the salt.

'These differences,' says Bunsen, 'observed in the absorption spectra of different didymium compounds cannot, in our complete ignorance of any general theory of the absorption of light in media, be connected with other phenomena; they remind one of the slight gradual alteration in pitch which the notes from a vibrating elastic rod undergo when the rod is weighted, or of the change of tone which an organ-pipe exhibits when the tube is lengthened.'

Sorby found that certain specimens of zircon exhibit distinct absorption-bands (*Chem. News*, xix. 121), and concluded that these were caused by the presence of a new metal, to which he gave the name of jargonium. More recently, however, he has found that the peculiar spectra are due to the presence of certain compounds of uranic oxide with zirconia. (See ZIRCON.)

Crooks's (*Proc. Roy. Soc.* xvii. 448) describes the spectra obtained by transmitted and reflected light from different varieties of opal; the absorption spectra exhibit dark bands identical in position with the bright lines obtained by reflection; both sets of lines show an irregular form, giving occasionally a spiral appearance, due probably to some irregularity in the cracks or laminae causing the interference-colours.

Our knowledge of the spectra of the metals has recently received an important addition from Thalén, who has carefully mapped the bright lines of the following rare metals: glucinum, zirconium, erbium, yttrium, thorium, uranium, titanium, tungsten, molybdenum, vanadium (*Nova Acta Reg. Soc. Upsal.* ser. iii. vol. vi. [1868]). The same observer has also determined the wave-lengths of the principal lines of forty-five metallic and non-metallic elements (*loc. cit.*).

The subject of the spectra of the metalloids (see Dictionary, vol. v. 388) has attracted much attention, and the difficulty of truly explaining the results is shown by the diversity of opinions respecting the nature of the double spectra. Thus Ångström (*Spectre normal du Soleil*, Upsala, 1868, p. 38; also *Phil. Mag.* [4] xlii. 395) states that the conclusions deduced by Plücker and Hittorf (Dictionary, v. 388) regarding the double spectra which many of the metalloids exhibit are not warranted, and that experiments made by him in conjunction with Thalén in no way bear out the opinion that one element can give totally different spectra. According to Ångström, 'the very reverse of this is true; that by successively augmenting the temperature we find that the intensity of the rays varies in a most complicated manner, and that accordingly even new rays can make their appearance if the temperature be sufficiently raised. But independently of all these mutations the spectrum of each substance always preserves its original character.' On the other hand, Frankland and Lockyer (*Proc. Roy. Soc.* xvii. 288, 453), Wüllner (*Pogg. Ann.* Dec. 1868; *Phil. Mag.* [4] xxxvii. 405), and Salet (*Phil. Mag.* [4] xlii. 318) describe certain important modifications which the spectra of hydrogen, nitrogen, and other metalloids undergo when the tension of the gas through which the spark passes is changed, and the temperature of the particles is thereby altered. Under certain conditions of temperature and pressure the hydrogen spectrum can be reduced to one line in the green, corresponding to the solar line F, whilst the complicated spectrum of nitrogen can likewise be reduced to one bright line in the green, with traces of other more refrangible faint lines (Frankland and Lockyer). The same phenomenon with respect to nitrogen had previously been observed by Huggins (*Phil. Trans.* 1868, p. 529; Roscoe's *Spectrum Analysis*, 2nd edit. 332). Wüllner fully describes the variation of the hydrogen spectrum with the pressure; when the tension of the gas is 135 mm. the tube shines with a whitelight of insufficient intensity to yield a visible spectrum; when the pressure is reduced to 100 mm. the light emitted is bluish-white, and gives a continuous spectrum, in which the lines H α [C] and H β [F] stand out. Under a pressure of 70 mm. the light is reddish-white, and the spectrum is continuous with H, α , β , and γ , visible, and also a series of beautifully shaded bands in the greenish and reddish yellow. This spectrum becomes more brilliant as the pressure diminishes to 30 mm. Under 21 mm. the lines H, α , β , and γ stand out brilliantly, and the shaded bands with the continuous spectrum become less intense. When the pressure is diminished to about 8 mm. the bands disappear and the continuous spectrum becomes almost invisible; under further rarefaction to 3 or 2 mm. the characteristic lines retain the same brightness, and everything else disappears almost entirely from the spectrum; yet with a simultaneous enfeeblement of the bright lines, part of the continuous spectrum reappears in the green. Hence it appears probable that the band spectrum of hydrogen belongs to a lower temperature than that in which the three lines alone are seen. The reappearance of the continuous spectrum with great rarefaction also bears out this hypothesis, inasmuch as the intensity of the current, and therefore the heating effect on the particles, diminishes by the greatly increased resistance of the highly rarefied gas. According to Wüllner, a still more remarkable change occurs when the hydrogen-tube is exhausted to the extreme limit of a Sprengel's pump; the light then suddenly becomes of a splendid green, like the light of a thallium flame, and the spectrum is quite changed. The line H α can scarcely be seen, and six splendid green lines appear on an almost black ground. This spectrum is always exhibited when the tube has attained the extreme degree of rarefaction of the Sprengel's pump, and if the discharge be continued for some time with the tube stop-cock closed, a continuous spectrum appears, but this on again exhausting (although no change of density in the gas occurs) yields the peculiar line spectrum just described. Wüllner has compared this spectrum with that of aluminium (of which metal the electrodes were composed), mercury, and other substances, traces of which might be present and might possibly cause the appearance observed, but he concludes from the non-coincidence of the green lines with those of the metals, &c., that these former are really due to hydrogen. Wüllner concludes that difference of temperature must in the case of hydrogen be regarded as the cause of the essentially different spectra observed, and hence that the emissive power of a substance may materially alter with the temperature. A similar series of observations have been made by Wüllner with oxygen; three distinct spectra may be obtained with induction-currents according as the oxygen in the tube has a greater or less density, and these three different spectra depend upon the temperature to which the particles of the oxygen are heated.

The comportment of nitrogen appears to be somewhat different; this gas furnishes two spectra, but these cannot be obtained one from the other by a simple change of density of the gas, the difference in temperature thus produced being insufficient to

change the spectrum, and this can only be effected by an alteration in the mode of discharge, such as the introduction of a Leyden jar. The singular fact of the thickening or broadening of the hydrogen lines, and especially of the line $H\beta$ [F], under certain conditions, was observed by Plücker, but Frankland and Lockyer concluded that this was due to diminution of pressure, 'and not appreciably, if at all, to temperature *per se*.'

In a recent communication (*Compt. rend.* Aug. 7, 1871) Ångström reasserts his conclusion that hydrogen and oxygen have each but one spectrum, that of hydrogen being the one found in the light of the sun and stars. He bases his opinion on the difficulty of obtaining any gas perfectly pure in an extreme state of rarefaction; thus on one occasion he rarefied air in a Geissler's tube as much as possible by a mercurial pump, causing the discharge of a Ruhmkorff's coil to pass through the tube, and obtained in succession the following spectra: (1) the ordinary air spectrum, (2) the fluted spectrum of nitrogen, (3) that of carbonic oxide, (4) the lines of chlorine and sodium. If the vacuum has been produced by mercury, the spectrum of this metal may be obtained; and if the gases are dried by sulphuric acid, the sulphur spectrum may make its appearance. Ångström then proceeds to criticise Wüllner's four different hydrogen spectra. One of these is the true hydrogen spectrum of fine bright lines, and this does change into one consisting of bright bands or into a continuous spectrum (as Ångström himself discovered in 1853) when a denser gas is used. The other two hydrogen spectra Ångström disposes of by showing that the spectrum of acetylene as observed by Berthelot is identical with one, whilst the other is identical with the sulphur spectrum.

As regards the two new spectra of oxygen found by Wüllner, Ångström shows that the lines of the one are identical with those of the oxide of carbon spectrum, whilst the other is beyond doubt the same as that of chlorine. Hence he concludes that we do not know as yet any other spectrum of oxygen beyond that discovered by himself in 1853, and examined with care by Plücker. The variation observed in the spectra of certain gases by the action of magnetism, Ångström ascribes, not to the existence of different spectra for one substance, but to the production by the magnetisation of new combinations or new substances, an action similar to that produced by inserting a condenser or Leyden jar in the circuit. Thus a Geissler's tube gave between the poles of an electromagnet the ordinary spectrum of carburetted hydrogen, whereas without the intervention of magnetism it gave the carbonic oxide spectrum without the hydrogen lines being visible; whilst another tube containing hydrogen obtained from water and dried over sulphuric acid, which gave Plücker's two hydrogen spectra, gave when under the influence of magnetism, the sulphur lines, which Wüllner believes to be a new hydrogen spectrum, whilst at the same time the carbonic oxide lines were seen near the poles.

Salet (*Compt. rend.* 1871, No. 9) has examined the spectrum of sulphur, and confirms Plücker's original discoveries, inasmuch as he concludes that two spectra of this metalloïd really exist, one composed of lines and the other of bands, the first produced by the disruptive discharge, and the second by discharges of less tension.

* Under certain conditions incandescent gases can, as we have seen, yield continuous spectra. Dibbitts (*Pogg. Ann.* cxii. 497) in 1864 showed that the oxyhydrogen flame yields a faint continuous spectrum, in which the bright lines of hydrogen and oxygen are not seen. And Frankland (*Proc. Roy. Soc.* xvi. 419) has proved that when the pressure under which the gases are burnt is much increased, a very considerable augmentation of the luminosity is obtained and a bright continuous spectrum is observed. A continuous spectrum is likewise obtained when many gases or vapours undergo combustion, and these considerations have led Frankland to conclude that the ordinary explanation given by Davy of the luminosity of flame is incorrect, and that the light is due, not to the incandescence of solid carbon, but to the combustion of highly condensed gaseous hydrocarbons.

It is to be remembered that although, under the conditions most generally met with, gases have been found to give discontinuous spectra, the Theory of Exchanges, upon the truth of which the science of spectrum analysis is founded, does not give us any information whether a gas yields a continuous or a broken spectrum. According to this theory, if a glowing gas absorbs some of each of the rays which fall upon it, it must emit a continuous spectrum. Even under diminished pressure many gases exhibit a continuous spectrum, as is seen in a flame coloured by soda or potash salt. Kirchhoff showed many years ago that when the temperature or density of a glowing gas is increased, and the luminosity of the spectrum becomes greater, the dark portions of the spectrum must increase in luminosity more rapidly than the bright portions. Hence it does not appear surprising that by increase of temperature and pressure the spectrum originally consisting of bright lines or bands upon a scarcely visible continuous

background should by degrees change into a spectrum exhibiting all the colours in equal intensity. H. St. Claire Deville (*Phil. Mag.* [4] xxxvii. 111) gives a somewhat similar explanation of the continuous spectra from incandescent gases, and does not endorse Frankland's conclusions concerning the source of luminosity of the candle-flame.

Atmospheric Lines and Spectra of the Moon and the Planets.—The existence of dark bands caused by atmospheric absorption was first pointed out by Brewster in 1833.

In 1865–6, J. P. Cooke junior (*Proc. Amer. Acad. Sc.* vii. Jan. 1866; and *Am. Journ. Sc. and Arts*, vol. xi. Nov. 1865) showed that many of the air lines are solely due to aqueous vapour contained in the atmosphere. Jansson produced these lines artificially by allowing the light from 16 jets of coal gas to pass through a column of high-pressure steam 37 metres in length. Groups of dark lines then appear in the spectrum between the extreme red and the lines D. These lines are found to coincide with lines in the solar spectrum which become intense when the sun is near the horizon. (For Jansson's map of these lines see Roscoe's *Lectures*, 2nd edition, p. 226.)

The Moon.—No signs of a lunar atmosphere presented themselves in a most accurate examination which Mr. Huggins made as follows: the spectrum of a star was carefully observed at the moment the dark edge of the moon passed over it. If an atmosphere existed in the moon, the observer would see the starlight by refraction after the occultation had occurred, and the red rays being less refrangible would disappear before the blue. All the differently coloured rays were found to disappear at the same instant, and hence the absence of a lunar atmosphere is to be inferred.

The Planets.—In the spectrum of Jupiter, lines are seen indicating an absorptive atmosphere about this planet. One strong band corresponds to a known elementary substance (hydrogen), whilst the same conclusion is arrived at with Saturn. Padre Secchi concludes from his own observations that in all probability the vapour of water exists in the planetary atmospheres. The red colour which distinguishes Mars is not derived from absorption in its atmosphere, as the light reflected from its polar regions is free from the red tint peculiar to the other portions of the planet (Huggins, *Monthly Notices R. A. Soc.* xxvii. 178).

Spectrum of Uranus.—Huggins (*Proc. Roy. Soc.* xix. 488) has observed the absorption-spectrum of the planet Uranus with his equatorial refractor of 15-inch aperture. This is characterised by six remarkably strong absorption-lines; the strongest of these has a wave-length of about 544 millionths of a millimetre; another at 572 is nearly as broad, but not so dark; the one a little less refrangible than D is narrower than the others. The most refrangible band is identical in position with the F line, and was proved to be coincident with the bright hydrogen line F, so that this band in the planet spectrum is probably due to hydrogen. Three of the bands were found not to differ greatly in position from the bright air lines, but there is no strong line in the spectrum of Uranus corresponding to the strongest of the air lines, viz. the double nitrogen line. The lines due to carbonic acid do not appear in the Uranus spectrum; there is no absorption-band in the position of the sodium line, nor are the lines in the spectrum of Uranus at the positions of the principal groups produced by absorption in the terrestrial atmosphere.

Terrestrial Atmospheric Absorption.—Lieut. J. H. Hennessey (*Proc. Roy. Soc.* xix. 1) has mapped on a more complete scale than has been hitherto done, the absorption-lines seen at Mussoorie in India when the sun is low. An accurate map of these lines from A to D accompanies the paper, many of which are found to be identical with the air lines mapped by Kirchhoff.

Spectroscopic Observations of the Sun.—A complete memoir on the 'Normal Solar Spectrum' (Upsala, 1868) has been published by A. J. Ångström of Upsala, accompanied by an atlas of six plates exhibiting the whole length of the solar spectrum from A to H. The positions of these lines are mapped according to their wave-lengths, which have been calculated from observations most carefully made with diffraction-spectra. The bright metal lines coincident with those of Fraunhofer are also given. The following table gives a summary of the solar lines shown on Ångström's maps as produced by known elements:

Substances	No. of Lines	Substances	No. of Lines
Hydrogen . .	4	Manganese . .	57
Sodium . .	9	Chromium . .	18
Barium . .	11	Cobalt . .	19
Calcium . .	75	Nickel . .	33
Magnesium . .	4 + 3 (?)	Zinc . .	2 (?)
Aluminium . .	3 (?)	Copper . .	7
Iron . .	450	Titanium . .	118

The presence of titanium in the solar atmosphere was discovered by Thalén. Many of these lines were formerly supposed to be due to calcium, having been obtained by the ignition in the electric arc of gas carbon impregnated with calcium chloride. The carbon however contained titanium, and 118 out of 170 of the observed titanium lines were seen to be coincident. Hence there can be very little doubt as to the existence of titanium in the solar atmosphere, and the well-known occurrence of this metal in meteoric stones seems to support the view that titanium possesses a general cosmical distribution. The total number of coincident solar lines now observed amounts to close upon 800, and this number might easily be increased by using more powerful means of raising the temperature of the substance under examination. Nevertheless, the number already mapped suffices to show that, to account for the origin of all the more prominent rays in the solar spectrum, we must assume that the substances constituting the chief mass of the sun are without doubt the same bodies as exist on our planet (Ångström).

Discoveries in Solar Physics made by means of the Spectroscope.—Since the publication of the last volume of this Dictionary, discoveries have been made with respect to the sun, second only in importance to Kirchhoff's original discovery; and the subject has been so largely developed that it is impossible in the present article to do more than refer to the most striking discoveries, leaving the reader to obtain further information from works specially devoted to spectroscopic astronomy. About five years ago J. Norman Lockyer (*Proc. Roy. Soc. Oct. 11, 1866*) suggested that it might be possible by the use of the spectroscope to obtain evidence of the presence of the red prominences which total eclipses have revealed to us in the solar atmosphere, although they escape all other means of observation on other occasions. After many fruitless attempts, Mr. Lockyer at last succeeded (Oct. 20, 1868) in seeing the prominences and in ascertaining the existence of three bright lines in the following positions: I. Absolutely coincident with C. II. Nearly coincident with F. III. Near D. These bright lines were rendered visible under the ordinary condition of the sun by employing a powerful spectroscope giving very large dispersion. The almost continuous spectrum given out by the limb of the sun was thus spread out until it became very feeble, whilst the luminous intensities of the monochromatic rays given out by the glowing gas were but slightly diminished, and thus the light from the prominences became visible without being interfered with by that emanating from the body of the sun.

M. Janssen, who was sent by the French Government to Guntoor in India to observe the total eclipse on August 18, 1868, saw and measured the position of these bright lines on that day, and, struck by their intensity, he likewise conceived the idea that they might be visible when the sun was un eclipsed. On the next day he succeeded in his endeavour, 'so that,' he writes, 'I have been working for the last seventeen days in a perpetual eclipse.' The announcement of this separate discovery was received by the French Academy on October 26, 1868, a few days after Mr. Lockyer's discovery was made known to the Royal Society. By employing a wide slit with an absorption-screen of ruby glass, Huggins (*Proc. Roy. Soc. xvii. 302*) succeeded (Feb. 13, 1869) in viewing a solar prominence so as to distinguish its form, and Mr. Lockyer finds that no absorptive medium is needed. Lockyer's investigations have not only shown that the red prominences are due to incandescent hydrogen, but that the whole body of the sun is enveloped in a glowing gaseous medium extending for 5000 miles in height, of which the prominences are only local aggregations.* This envelope he terms the *Chromosphere*, to distinguish it from the cool absorbing atmosphere on the one hand and the light-giving photosphere on the other. Under proper instrumental and atmospheric conditions the spectrum of the chromosphere is always visible in every part of the sun's periphery. The bright line identical in position with Fraunhofer's

* The existence of a coloured red atmosphere surrounding the sun appears to have been first observed by Grosch during the total eclipse of August 29, 1867, near Santiago (*Astron. Nachrichten*, No. 1737, Jan. 28, 1869).

'F' was found invariably to expand as the sun is approached, whilst the 'C' and 'D' lines do not expand. A similar widening of the bright F line was observed by Plücker when the pressure of the incandescent hydrogen is considerably increased. Frankland and Lockyer have confirmed this observation, and they believe that we have thus a means of ascertaining the tension of the various elevations of the solar chromosphere. Lockyer has also succeeded in detecting the third (blue) line of hydrogen, viz. 2796 on Kirchhoff's scale, in the light of the chromosphere, and hence, with the exception of the bright yellow line (more refrangible by 8 or 9 of Kirchhoff's degrees than the lines 'D'), the observed spectrum of the prominences and of the chromosphere corresponds exactly with the spectrum of hydrogen under different conditions of pressure. The nature of this yellow line has not yet been ascertained, though Frankland and Lockyer conceive that it may possibly be due to hydrogen in a more intense state of ignition than has yet been obtained.

The spectroscopic examination of the solar spots by Lockyer has definitively settled the long-disputed point concerning the nature of these singular phenomena. According to M. Faye, a spot is dark because it is a hole in the photosphere, and the feebly luminous, and therefore feebly radiating interior gases of the sun are seen. English observers (Messrs. De la Rue, Stewart, and Loewy) infer that the spot is dark because the solar light is absorbed by a cool non-luminous absorbing atmosphere pouring down on to the photosphere. If the first theory is correct, the spot-spectrum should indicate only bright lines; if the second is true, the spot-spectrum must differ from the ordinary solar spectrum by either a general or partial diminution of intensity. The spectroscope shows that a sun-spot is a region of greater absorption, but that in the bright portions adjacent to the spot bright lines are occasionally seen, showing the injection of intensely ignited photospheric gases into the chromosphere; indeed certain of these bright hydrogen lines can be generally seen in the solar spectrum itself. These facts appear to indicate that the absorption producing Fraunhofer's lines occurs either in or extremely near to the photosphere, and not in a remoter cooler atmosphere; indeed the *bright* lines of magnesium, sodium, iron, and barium are not unfrequently seen in the chromosphere, the incandescent vapours of these metals being thrown up by convection currents into the higher regions of the solar atmosphere. Indeed on one occasion Lockyer saw *hundreds* of the Fraunhofer lines beautifully bright at the base of a prominence. The bright lines when thus seen appear as very short and very thin lines, generally much thinner than the corresponding dark Fraunhofer's lines.

'It does not follow that the largest prominences are those in which the intensest action or the most rapid change is going on, the action as visible to us being generally confined to the regions just in or just above the chromosphere; the changes arising from violent uprush or rapid dissipation—the uprush and dissipation representing the birth and death of a prominence' (Lockyer). About 9^h 45' on March 14, 1869, Mr. Lockyer observed a fine dense prominence near the sun's equator, on the eastern limb, with signs of intense action going on. At 11^h 5' the height of this prominence was 1' 5", or 270,000 miles. At 11^h 15' the whole of this prominence had disappeared without leaving a trace behind. The bright lines of magnesium, sodium, barium, and iron seen in the chromosphere are thinner than the usual Fraunhofer's lines, but the dark lines of these metals seen in the spots are *thicker* than the corresponding Fraunhofer's lines. This thickening of the line appears to indicate a *downrush* at those places, and a consequent diminution of pressure and temperature, which causes a thickening of the absorption lines. The variation in the selective absorption of sodium vapour under variation of the thickness of the layer, and increase of the tension of sodium vapour, can be shown by heating some sodium in a glass tube placed before the slit of the spectroscope; in the cooler parts of the tube, where the vapour is present in small quantities, the absorption is indicated by a narrow double line; where the sodium vapour is present in larger quantity, the dark line becomes broad, as is seen in the spectrum of a spot. The velocity with which the hydrogen is moving in the cyclonic storms of the photosphere, which cause the solar spots, can be ascertained by the deviation which the F line exhibits, sometimes towards the red, showing motion on the sun's surface of retrogression or downward action; sometimes towards the violet, showing motion of approach or an upward action. If the solar limb be observed, a motion of a cyclonic or lateral nature on the sun's surface will produce the same effect. The strange contortions which the F hydrogen line undergoes at the centre of the sun's disc are very remarkable; not only does the line appear bright, but the dark one is twisted in places, generally inclining towards the red; and often when this happens we have a bright line on the violet side. Sometimes the line stops short of one of the small sun-spots; swelling out prior to disappearance; invisible in a facula between two small spots; changing into a

bright line, and widened out on both sides two or three times in the very small spots; becoming bright near a spot, and expanding over it on both sides; very many times widened out near a spot, sometimes considerably, on the less refrangible side; and finally extended as a bright line without any thickening over a small spot (Lockyer).

Measuring the deviation of the line thus noticed, by means of Ångström's map, in ten-millionths of a millimetre, Lockyer has frequently noticed a deviation corresponding to a velocity of 20 miles per second. On one occasion the F line was seen to be triple, showing that the hydrogen on the sun's surface under observation was moving with very different velocities, the extreme alterations of wave-length corresponding to the enormous velocity of 120 miles per second—if the explanation thus given be in reality the correct one.

The spectroscopic changes which are thus seen are sometimes connected with telescopic ones. Thus, on April 21, at 7.30 A.M., a tremendous action was observed in a prominence, for the lines C, D, and F were magnificently bright in the ordinary spectrum itself over the spot-spectrum. The injection into the chromosphere surpassed everything previously seen, as there was a magnesium cloud quite separated from the limb, and high up in the prominence itself. The photographic picture of the solar disc, made at Kew on the same day at 10.55 A.M., showed that an area of great disturbance surrounded the spot, and a subsequent photograph, at 4.1 P.M., showed the limb to be actually broken in that particular place; the photosphere seemed to have been actually torn away behind the spot, exactly when the spectroscope had afforded to Lockyer evidence of a cyclone.

F. Zöllner (*Pogg. Ann.* cxxvii. p. 624) has also noted some very interesting facts respecting the enormously rapid motion of the protuberances, and accompanying the paper are a series of drawings showing the changes which the red flames undergo.

For the description of the phenomena observed in a total eclipse, especially on the nature of the corona, works on spectroscopic astronomy may be consulted. It may here be stated that the spectrum of the corona contains one bright green line identical in refrangibility with an iron line marked 1474 on Kirchhoff's scale.

Further Spectroscopic Researches on the Stars, Nebulae, and Comets by W. Huggins.—Dr. Huggins (*Phil. Trans.* 1868, p. 529), by employing a much more powerful train of prisms than he had previously used, endeavoured to ascertain whether any deviation in the position of the nebular or stellar lines was visible, which deviation, if it existed, would, according to Doppler's theory, indicate motion with respect to these bodies and the earth. The first object examined was the great nebula in Orion; the brightest line of the nitrogen spectrum (which can be so reduced in luminosity as to leave only this line visible) was found to be coincident with the nebular line within the limits of observational error, so that Huggins concludes that the nebula is not receding from the earth with a velocity greater than 10 miles per second, and that it is not approaching the earth with a velocity greater than 25 miles per second. The position of the F line in the Sirius-spectrum was next carefully examined; this was found to be broader than the corresponding hydrogen line, and also broader than the dark solar line F. The position of the Sirius F line is slightly less refrangible than the hydrogen line, and Huggins believes that this may be received as representing a motion of recession between Sirius and the earth, amounting to 41.4 miles per second; or, subtracting the earth's proper motion, we have a motion of recession of 29.4 miles per second, which we appear entitled to attribute to Sirius.

The spectrum of Comet II., 1868, has also been examined by Dr. Huggins; this consisted of 3 bands, identical in position with the bands obtained by passing the spark through olefiant gas, and hence it appears that incandescent carbon, either in the free or possibly in the combined state, exists in cometary matter. The spectrum of Comet I., 1871, has also been examined by Huggins, who concludes that it possesses a constitution similar to those of 1868.

Variable Stars.—The spectrum of γ Cassiopeiae appears to be in some respects at least analogous to that of T Coronae (v. 395). In addition to the bright line near the boundary of the green and blue observed by Padre Secchi, there is a line of equal brilliancy in the red and dark absorption lines. Huggins has shown that these bright lines are coincident with the lines C and F, showing the presence in this star of incandescent hydrogen. MM. Wolf and Rayet have also observed bright lines in several other small stars. Padre Secchi (*Astronomische Nachrichten*, Jan. 28, 1869) finds it possible to class stars into four groups, each characterised by a special form of spectrum. Group 1 contains the white stars Sirius, α Lyrae, Vega, &c., whose spectrum is characterised by four black lines coincident with those of hydrogen. Group 2 contains the yellow stars, having spectra intersected by numerous fine lines resembling those of our sun; in this group Secchi reckons Pollux, Capella,

γ Aquilæ, and our Sun. The 3rd group contains the red and orange stars, α Orionis, α Herculis, β Pegasi, &c., the spectra of which are divided into 8 or 10 parallel columnar clusters of dark and bright bands increasing in intensity towards the red. Group 4 is made up of the small red stars, whose spectra are distinguished by a succession of three bright zones, increasing in intensity towards the violet. Out of 316 stars examined, Secchi found that 164 belonged to the first group, and 140 to the second, whilst the few remaining constituted the third and fourth classes.

Spectra of the Aurora Borealis and of the Zodiacal Light.—Ångström (*Spectre normal du Soleil*) and O. Struve have observed the spectrum of the aurora. This light is found to be monochromatic; one brilliant band situated to the left of the green calcium lines only is seen. Ångström found the wave-length of this ray to be 5567 (ten millionths of a millimetre). The same observer also succeeded in observing the same bright band in the spectrum of the zodiacal light, and during a star-light night, when the sky appeared almost phosphorescent, traces of this band were visible from all parts of the heavens. This bright band does not coincide with the known rays of any simple or compound body yet examined.

Recent General Literature on the Subject.—Roscoe's *Lectures on Spectrum Analysis, with Lithographic Copies of the Maps of Kirchhoff, Ångström, and Huggins* (Macmillan), 2nd edition, 1870. Schellen, *Die Spectralanalyse*, Braunschweig (Westermann), 1870; English translation, 1871. Secchi, *Le Soleil*, Paris, 1870. Proctor, *The Sun* (Longmans), 1871. Delaunay, *Analyse spectrale, Annuaire du Bureau des Longitudes*, 1869. R. P. A. Secchi, *Sugli Spettri dei Corpi Celesti*, Memorie, Roma, 1868; *Spettri delle Stelle fisse*, Mem. I. and II. Ångström, *Recherches sur le Spectre normal du Soleil*, Upsala, 1868. A full list of memoirs on spectrum analysis is given at the end of Roscoe's *Lectures*. H. E. R.

SPHERITE. An hydrated aluminium phosphato occurring on hematite at Zajecan, north of St. Benigna, in isolated or botryoidally grouped spherules of light grey colour, passing more or less into red and blue. Sp. gr. 2.53. Hardness 4. Its analysis gave:

P ₂ O ₅	Al ₂ O ₃	H ₂ O	MgO	CaO	SiO ₂	
28.58	42.36	21.03	2.61	1.41	0.87	= 99.86

leading (after deduction of the lime and magnesia as phosphates) to the formula $5Al_2O_3 \cdot 2P_2O_5 + 16H_2O$ (Zepharovich, *Jahresb.* 1867, p. 1001).

SPHEROSIDERITE. This mineral, occurring in the Anamesito district of the lower Mainthal, near Steinheim, mostly in spherical or botryoidal masses, was found by Hornstein (*Jahresb.* 1867, p. 1006) to contain:

FeO	CaO	MgO	MnO	CO ₂	
61.25	0.02	0.61	trace	38.12	= 100.

STAFFELITE. A calcic phosphate mixed with carbonate, fluoride, &c., occurring as an incrustation on phosphorite at Staffel, also in the Jura limestone at Erzberg near Amberg (Stein, *Jahresb.* 1866, p. 917; Petersen, *ibid.* 1867, p. 1002).

STARCH. Observations on the occurrence and behaviour of starch, or an amylaceous substance, in the lactent vessels of various *Apocynaceæ*, have been made by Trécul (*Compt. rend.* lxi. 156); on the starch-granules in *Floridaceæ* and *Corallinaceæ* by van Tieghem (*ibid.* 512). C. Dareste (*ibid.* lxiii. 1142) found in egg-yolk a considerable number of microscopic granules, which were coloured by iodine, and were very much like starch in form and structure.

Flückiger (*Zeitschr. anal. Chem.* v. 302) has determined the sp. gr. of starch from arrowroot and potatoes by means of petroleum. These results are:

	Arrowroot.		Potato-starch.	
	Air-dried	Dried at 100°	Air-dried	Dried at 100°
Sp. gr. at 17°-18° . . .	1.5045	1.5684	1.5029	1.6330

According to Payen (*Compt. rend.* lxi. 512; *Jahresb.* 1865, p. 596), starch immersed in a saturated solution of potassium bromide or iodide swells up to a pasty mass of 25 to 30 times its original bulk, which dissolves in water, leaving a very small quantity of membrane; iodine-water added to the solution throws down iodide of starch in flocks. As cellulose is not attacked by bromide or iodide of potassium, Payen regards these salts as well adapted for the detection of starch in vegetable tissues. Iodide of starch, precipitated from its aqueous solution by potassium chloride, and then decolorised by a small quantity of ammonia, loses in the course of an hour the power of recovering its colour on addition of acetic acid; when precipitated by sodium chloride

it retains this power longer. On the decoloration of iodide of starch, see also Magne Lahens, *Bull. Soc. Chim.* [2] vi. 79; *Jahresh.* 1866, p. 664.

Conversion of Starch into Glucose and Dextrin.—It is generally supposed that in the action of acids or of diastase upon starch, the starch is first converted into dextrin by a mere alteration of physical structure, and that the dextrin is then converted into glucose by taking up the elements of water, this second stage of the process occupying a much longer time than the first; but from the experiments of Musculus (*Compt. rend.* 1. 785; liv. 194; *Ann. Ch. Phys.* [3] lx. 208) it appears that both dextrin and glucose are produced at the very commencement of the reaction, and always in the proportion of 1 mol. glucose to 2 mol. dextrin, whence it may be inferred that the molecule of starch contains $C^{18}H^{30}O^{15}$, and that it is resolved into glucose and dextrin by taking up 1 mol. water:

When the conversion is effected by a dilute acid, the dextrin is, after several hours' boiling, completely converted into glucose; but when diastase is used as the converting agent, the production of glucose goes on only so long as there is any unaltered starch still present, the dextrin undergoing no further alteration. These views have been contested by Payen (*Compt. rend.* liii. 1217; *Ann. Ch. Phys.* [4] iv. 286; *Jahresh.* 1861, p. 717; 1865, p. 597), who finds that diastase really possesses the power of converting dextrin into sugar, but that the conversion ceases as soon as a certain quantity of sugar has been produced; if however the sugar be removed as fast as it is formed, as in alcoholic fermentation, the transformation of the dextrin into sugar recommences, and goes on nearly to completion. Under favourable circumstances of the action of diastase on dextrin, a product may be obtained containing more than 50 per cent. of sugar. Musculus, on the other hand (*Ann. Ch. Phys.* [4] vi. 177), adheres to his view of the unalterability of pure dextrin by diastase, and endeavours to show that the formation of sugar observed by Payen was due to the presence of amylaceous substance in the dextrin submitted to experiment. According to O. Philipp (*Bull. Soc. Chim.* [2] viii. 363), dextrin and glucose are not formed in constant proportions in the action of dilute sulphuric acid upon starch, as asserted by Musculus, but the proportion of glucose increases under otherwise equal circumstances with the quantity of acid employed. This however is quite in accordance with the known fact—not denied by Musculus—that dextrin is gradually converted into glucose by the action of dilute acids.

STEAROLIC ACID. $C^{18}H^{32}O^2$ (Overbeek, *J. pr. Chem.* xevii. 159).—Produced by heating monobromoleic acid or oleic dibromide to 100° with at least 2 mol. potassium hydrate in alcoholic solution, and may be separated from the dilute decanted solution by hydrochloric acid. It crystallises from alcohol in silky needles or long prisms, melts at 48° , and distils at 260° , for the most part undecomposed. The salts are mostly well crystallised and become strongly electric by friction. The barium salt is anhydrous; the calcium salt contains $(C^{18}H^{31}O^2)_2Ca + H^2O$; the silver salt, $C^{18}H^{31}O^2Ag$, is a crystalline precipitate.

Stearolic acid is not affected by nascent hydrogen. In contact with bromine it forms *stearolic dibromide* (or dibromoleic acid), $C^{18}H^{32}Br^2O^2$, which when pure is a nearly colourless heavy oil, soluble in alcohol and ether, but insoluble in water. *Stearolic tetrabromide* (or tetrabromostearic acid), $C^{18}H^{32}Br^4O^2$, produced by the action of bromine in excess on stearolic acid in sunshine, crystallises in large white laminae, which melt at about 70° , and soften even when rubbed. Both these bromine-compounds are decomposed by prolonged heating with alcoholic potash, forming stearolic acid, and a liliac acid not yet examined.

Stearolic acid fused with excess of potash at a rather high temperature is converted into myristic acid, $C^{14}H^{28}O^2$; at a lower temperature, if the action be arrested as soon as gas begins to escape, it yields an acid, $C^{16}H^{30}O^2$, isomeric or identical with hypogaeic acid (Marasse, *Zeitschr. f. Chem.* [2] v. 671).

STEAROXYLIC ACID, $C^{18}H^{32}O^4$, is formed, together with azelaic acid and azelaic aldehyde, by dropping fuming nitric acid into cooled stearolic acid, and remains in the residue left on treating the semifluid mass with water. It crystallises from alcohol in faintly yellowish oblique rhombic tables, slightly soluble in cold alcohol, easily in hot alcohol and in ether, melting at 86° , and scarcely decomposing at 200° . It is monobasic and does not unite directly with bromine. Its *silver salt*, $C^{18}H^{31}O^4Ag$, is precipitated on mixing the acid with silver nitrate in hot alcoholic solution, as a white crystalline powder which does not decompose at 100° . The *barium salt*,

($C^{10}H^{11}O^4$) 2Ba , is a viscid precipitate becoming pulverulent in contact with ether (Overbeck).

STETEFELDITE. A silver ore occurring in the Empire District in the southern part of the State of Nevada, accompanying fine-grained galena, and usually imbedded in quartz, more rarely accompanied by copper-silver glance and cupric antimonate. It is massive or in thick veins; has an uneven, sometimes conchoidal fracture; hardness 3.5 to 4.5, sp. gr. 4.2, and a slate-black to blue-black colour. Its analysis gave:

Ag	Cu	S	CuO	PbO	FeO	Sb 2 O 3	H 2 O	AgCl
5.75	7.78	1.30	16.05	15.94	1.76	45.08	10.29	2.38 = 100.33

(Riotte n. Stetefeld, *Jahresb.* 1867, p. 1003).

STILBENE. $C^{14}H^{12}$, is formed by the action of sodium-amalgam on the product of the decomposition of deoxybenzoin by phosphorus pentachloride. (See Benzoin, p. 332.)

STRYCHNINE. $C^{21}H^{22}N^2O^2$.—This alkaloid occurs in small quantity, together with a large quantity of brucine, in *Lignum colubrinum* (Berlekom, *Zeitschr. f. Chem.* [2] ii. 443).

The following method of estimating strychnine and brucine in poison-nuts and other strychniferous drugs, founded on the solubility of the free bases and the insolubility of their sulphates, in benzol, is given by Dragendorff (*Zeitschr. f. Chem.* [2] ii. 27). The pulverised nuts are repeatedly boiled with very dilute sulphuric acid, and the extract, neutralised with magnesia and evaporated to a syrup, is heated to boiling, first with alcohol of 90 p. c. and then with alcohol of 50 p. c. The alcoholic solution evaporated to one-fifth of its bulk and neutralised with dilute sulphuric acid (free from nitric acid) yields to benzol a small quantity of fat, together with an odoriferous substance soluble in pure and in acidulated water; and if it be then again neutralised with magnesia, and agitated with benzol, the strychnine (together with brucine) is dissolved, and remains on evaporating the benzol. Poison-nuts thus treated yield on the average 2.3 p. c. strychnine containing bromine.

130 pts. of the following liquids dissolve of crystallised strychnine:

	Benzol.	Amyl Alcohol.	Ether.	Alcohol of 95 p. c.
Strychnine	0.607	0.55	0.08	0.936 pt.

The recently precipitated base is more soluble.

To detect strychnine in animal fluids (blood, extracts of tissues, urine, &c.), Cloetta (*Zeitschr. anal. Chem.* v. 265) precipitates the liquid with basic lead acetate (after removing the albumin by boiling), and evaporates the filtrate freed from lead to dryness. The residue, supersaturated with ammonia, is agitated after standing for 24 hours with twice its volume of chloroform, which when separated from the watery layer is left to evaporate. If strychnine is present, there remains a bitter residue, which, when dissolved in a small quantity of water containing nitric acid, and mixed with two drops of potassium dichromate, gradually deposits crystals of strychnine-chromate, which immediately gives the characteristic deep violet colour with sulphuric acid. By this method $\frac{1}{10}$ of a grain of strychnine may be detected with certainty in 650 c. c. of urine.

On the detection of strychnine in beer, see R. Wagner (*Zeitschr. anal. Chem.* vi. 387; *Jahresb.* 1865, p. 738).

On the resistance of strychnine to putrefaction, see Cloetta, *Zeitschr. anal. Chem.* v. 265; —Rieckler, *Vierteljahrs. pr. Pharm.* xii. 189; *Jahresb.* 1868, p. 756.

A boiling alcoholic solution of strychnine and zinc-chloride, mixed with a little hydrochloric acid and filtered, solidifies to a pulp of iridescent quadratic tables of the salt $2(C^{21}H^{22}N^2O^2.HCl).ZnCl^2$. By spontaneous evaporation of the alcoholic solution, this salt is obtained in vitreous prisms containing 1 mol. water (Gräffinghoff, *Bull. Soc. Chim.* [2] iv. 391).

Iodine-compounds of Strychnine.—The *periodide*, $C^{21}H^{22}N^2O^2.II.I^2$, discovered by Tilden (v. 411), separates on mixing strychnine nitrate with a solution of iodine in potassium iodide, in red-brown crystalline flocks, or from very dilute solutions in gold-yellow needles; from alcohol it crystallises in long dark-brown needles with bluish metallic lustre. The crystals are dichroic in polarised-light, appearing deep brown when their longitudinal axis is parallel to the plane of polarisation, light yellow when it is perpendicular thereto. They dissolve in 14,000 pts. of water at 15°, are moderately soluble in hot alcohol, slightly in chloroform, nearly insoluble in ether and carbon bisulphide. Aqueous ammonia separates strychnine from the compound, and potassium cyanide decolorises the alcoholic solution, the liquid after some time

depositing radiate groups of needles. The *mercury-compound* $C^{21}H^{22}N^2O^2 \cdot HI \cdot HgI^2$ is produced by agitating a hot alcoholic solution of the tri-iodide with mercury. It is insoluble in water, very slightly soluble in hot alcohol, from which it crystallises in light yellow shining tables. Similar crystallised double salts are obtained by heating the solution of strychnine tri-iodide with zinc and magnesium. *Methyl-strychnine tri-iodide*, $C^{21}H^{22}N^2O^2 \cdot CH^3 \cdot I^3$, crystallises from an alcoholic solution of 1 mol. methyl-strychnine hydriodide and 1 mol. iodine, in long brown-yellow needles, which in polarised light appear pale yellow or purple-red. *Ethyl-strychnine tri-iodide*, $C^{21}H^{22}N^2O^2 \cdot C^2H^5 \cdot I^3$, crystallises from alcohol in long four-sided needles exhibiting similar appearances in polarised light. The same is true of the *amyl-compound* $C^{21}H^{22}N^2O^2 \cdot C^5H^{11} \cdot I^3$. From a solution of the latter in tincture of iodine, the *pentiodide*, $C^{21}H^{22}N^2O^2 \cdot C^5H^{11} \cdot I^5$, crystallises in almost black needles exhibiting under the microscope by reflected light the lustre of polished steel. In polarised light they appear opaque when their axis is parallel to the plane of polarisation, dark purple-violet in the perpendicular position (Jørgensen, *Ann. Ch. Phys.* [4] xi. 115; *Jahresb.* 1867, p. 525).

A compound of strychnine with *hydrogen persulphide*, $C^{21}H^{22}N^2O^2 \cdot H^2S^4$, is obtained by mixing a cold-saturated solution of strychnine in strong alcohol with an alcoholic solution of ammonium sulphide containing free sulphur, and separates gradually in orange-red needles, which, after decantation of the mother-liquor, may be washed with cold alcohol. They are perfectly insoluble in water, alcohol, ether, and carbon bisulphide. Strong sulphuric acid decolorises them, and on adding a little water, hydrogen persulphide separates in oily drops, while the solution contains strychnine sulphate (Hofmann, *Deutsch. chem. Gesellschaft. Berlin*. 1868, p. 81; *Zeitschr. f. Chem.* [2] iv. 502). See also H. How (*Chem. News*, xviii. 232).

Methyl-strychnine is much less poisonous than strychnine. The nitrate given in doses of 0.05 to 0.2 grm. does not act poisonously on dogs or rabbits when taken internally; by subcutaneous injection it produces symptoms of paralysis similar to those produced by curara (Schroff, *Jahresb.* 1866, p. 474). The hydriodide of the same base produces, not tetanus, but paralysis, like curara. 20 grains administered subcutaneously killed a rabbit; 30 grains introduced into the stomach produced no effect. The sulphate was much more active, but did not cause death by subcutaneous injection in doses of less than a grain (Crum Brown and Fraser, *Edinb. Phil. Trans.* vol. xxv.; *Jahresb.* 1868, p. 756).

STYPHNIC ACID. Syn. with OXYPICRIC ACID (p. 892).

STYROL. Syn. with CINNAMENE (p. 465).

SUBERIC ALDEHYDE, $C^8H^{14}O^2$, is formed, together with suberic acid and palmitoxylic acid, by the action of fuming nitric acid on palmitic acid (p. 895):

The suberic acid is extracted from the product by boiling water; the residue is dissolved in hot alcohol; and the lower dark-coloured oily layer which separates from the filtrate on cooling, and consists chiefly of suberic aldehyde, is separated from the supernatant solution of palmitoxylic acid, gently warmed to expel the alcohol, then distilled in a stream of aqueous vapour. The oil which floats on the watery distillate is dissolved in alcohol, and the solution is evaporated in a vacuum, whereupon the suberic aldehyde remains as an oil having a faint odour. It boils with partial decomposition at 202° ; leaves a difficultly combustible cinder when quickly heated on platinum foil; and is converted by oxidising agents (bromine and water) into a crystalline acid having the appearance and melting point of suberic acid (Schröder, *Jahresb.* 1866, p. 327).

SUCCINIC ACID. $C^4H^4O^4$.—This acid exhibits two modifications, corresponding to those of chloropropionic and of lactic acid (p. 969); viz.,

the former corresponding to β -chloropropionic and paralactic acid, the latter to α -chloropropionic and ordinary lactic acid.

Ordinary succinic acid is formed by heating phenaconic acid to 150° in a sealed tube with hydriodic acid of 50 p. c.; slowly also by the action of dilute hydriodic acid or of sodium-amalgam: $2\text{C}^2\text{H}^3\text{O}^4 + \text{H}^2 = 3\text{C}^2\text{H}^3\text{O}^4$.

The ethylic ether of ordinary succinic acid is produced by the action of ethyl monochloracetate on the product of the action of sodium on acetic ether (ethylic sodacetate, $\text{CH}^3\text{Na} \cdot \text{CO}^2\text{C}^2\text{H}^3$, or acetate of ethylene-sodium, $\text{NaC}^2\text{H}^4 \cdot \text{C}^2\text{H}^3\text{O}^2$):

(Noeldecke, *Ann. Ch. Pharm.* cxlix. 224).

Isosuccinic or α -succinic acid is prepared from α -chloropropionic acid by distilling the ethylic ether of the latter with potassium cyanide, whereby it is converted into α -cyanopropionic ether, $\text{CH}^3 - \text{CH}(\text{Cy}) - \text{COOC}^2\text{H}^3$, and boiling this ether with potash; β -succinic or ordinary succinic acid is obtained in like manner from β -chloropropionic acid (H. Müller, *Ann. Ch. Pharm.* cxxxi. 108;—Wichelhaus, *Zeitschr. f. Chem.* [2] iii. 247). Ordinary succinic acid is also produced by heating either ethylic chloride (v. 454) or ethylidene chloride with potassium cyanide to 160° – 180° ; and boiling the product with potash; in the latter case it is probable that the ethylidene is converted into ethylene during the action of the potassium cyanide on the chloride (Maxwell Simpson, *Compt. rend.* lxx. 351; see also Mühlhäuser, *Zeitschr. f. Chem.* [2] iii. 593; v. Richter, *ibid.* iv. 451). Other modes of formation of ordinary succinic acid are: *a.* By oxidation of benzoic acid with dilute sulphuric acid and lead dioxide, and in the animal organism (Meissner a. Shepard, *Jahresb.* 1866, p. 397).—*b.* By oxidation of paraffin with strong nitric acid (Gill a. Mensel, p. 708).—*c.* By the action of powerful reducing agents, *e.g.* saturated hydriodic acid at 150° – 180° , or tin and hydrochloric acid, on trichlorophenomalic acid, $\text{C}^6\text{H}^3\text{Cl}^3\text{O}^3$ (p. 917), this acid being first converted into phenomalic acid, $\text{C}^6\text{H}^3\text{O}^3$, and the latter resolved into succinic acid, and a body having the composition of acetic aldehyde: $\text{C}^6\text{H}^3\text{O}^3 = \text{C}^2\text{H}^3\text{O}^4 + \text{C}^2\text{H}^3\text{O}$ (Carius).

Isosuccinic acid melts at 130° , and dissolves in 5.4 pts. of cold water, whereas ordinary succinic acid melts at 170° – 180° , and requires more than 20 pts. of cold water to dissolve it (Wichelhaus). According to Carius (*Jahresb.* 1866, p. 564), 100 pts. of water dissolve 3.52 pts. of ordinary succinic acid at 15° ; 5.19 pts. at 17° ; 6.15 pts. at 18° .^{*} Isosuccinic acid in the form of sodium salt does not form a precipitate with ferric chloride (Wichelhaus), whereas succinic acid gives a red-brown precipitate (v. 455).

Isosuccinic acid heated to 150° does not yield an anhydride, like the ordinary acid, but is completely resolved into carbon dioxide and propionic acid: $\text{C}^4\text{H}^4\text{O}^4 = \text{CO}^2 + \text{C}^2\text{H}^3\text{O}^2$. Heated with bromine and water, it is converted much more easily than ordinary succinic acid into a monobrominated acid which, when treated with ammonia, appears to yield aspartic acid.

Isosuccinates.—A solution of the acid neutralised with an alkali is not precipitated by barium or calcium chloride. The free acid forms with lead acetate and silver nitrate, curdy precipitates which dissolve when heated. The potassium salt forms a mass of needle-shaped crystals. The barium salt, $\text{C}^4\text{H}^3\text{O}^4\text{Ba} + 2\text{H}^2\text{O}$, the calcium salt, $\text{C}^4\text{H}^3\text{O}^4\text{Ca} + \text{H}^2\text{O}$, and the zinc salt, $\text{C}^4\text{H}^3\text{O}^4\text{Zn} + 3\text{H}^2\text{O}$, produced by boiling the acid with the respective carbonates, are obtained by evaporation as indistinctly crystalline masses, which give off their water with decomposition when heated the barium and calcium salts at 200° , the zinc salt at 115° (V. v. Richter, *Zeitschr. f. Chem.* [2] iv. 452).

A solution containing 5 p. c. succinic acid and 1 p. c. uranic succinate turns green when exposed to sunshine, and gradually gives off carbon dioxide, leaving propionic acid in solution (Seekamp, *Ann. Ch. Pharm.* cxxxiii. 253).

Aqueous succinic acid slowly reduces potassium permanganate at the boiling heat also in presence of sulphuric acid. Heated to 100° with a solution of the permanganate containing a considerable quantity of potash, it yields oxalic acid (Berthelot *Bull. Soc. Chim.* [2] viii. 390).

^{*} The old determination by Lecanu a. Serbat (v. 454) must be regarded as erroneous.

Succinic acid heated with *hydriodic acid* is converted into butane:

(Berthelot, *Jahresb.* 1867, p. 345).

Isodibromosuccinic acid is formed, together with a small quantity of ordinary dibromosuccinic acid, and other products, by heating phenaconic acid in sealed tubes with excess of bromine and a small quantity of water (Carius, p. 905):

Thiosuccinic Acid, $\text{C}^4\text{H}^4\text{O}^2\text{S}^2$.—The potassium salt of this acid, $\text{C}^4\text{H}^4\text{O}^2\text{S}^2\text{K}^2$, is obtained by the action of potassium sulphhydrate on succinyl-phenol (p. 1042), both dissolved in absolute alcohol. It crystallises in tufts of pointed needles, dissolves very easily in water, with fall of temperature, easily also in alcohol and ether. The solutions, especially the aqueous solution, decompose by spontaneous evaporation in contact with the air, leaving gummy residues having an alliaceous odour. The recently prepared solutions act on metallic salts, like the solutions of alkaline sulphides. They are quickly decomposed by acids, with evolution of hydrogen sulphide, and if concentrated, deposit thiosuccinic acid in oily drops which soon crystallise (Weselsky, *Dent. chem. Ges. Ber.* ii. 518; *Zeitschr. f. Chem.* [2] v. 61).

Thiosuccinyl, $\text{C}^4\text{H}^4\text{O}^2\text{S}$, is formed by decomposing an aqueous solution of potassium thiosuccinate with hydrochloric acid:

The product is agitated with ether, and the ethereal extract is separated, dried with calcium chloride, and distilled. There then remains an oily residue, which when left over potash under the air-pump, solidifies to a broadly laminar crystalline mass, which remains moist for a long time. Thiosuccinyl dissolves easily in water, alcohol, and ether, has a strong acid reaction, a very sweet taste, with an after-taste like that of succinic acid, and melts at 31° . Its solution gives with lead acetate a yellow precipitate quickly turning brown, black when heated, and settling as a specular deposit on the sides of the vessel. From solution of cupric sulphate it immediately precipitates copper sulphide. With silver nitrate it forms a white precipitate, which soon turns yellow and finally black; with ferric chloride a milky turbidity, which increases to a white precipitate, turning grey when heated, and black on addition of ammonia (Weselsky).

SUCCINIMIDE. $\text{C}^4\text{H}^5\text{NO}^2 = (\text{C}^4\text{H}^4\text{O}^2)^{\cdot}\text{NH}$.—The melting point of this compound has hitherto been given at 210° on the authority of Fehling and of Teuchert (v. 461). Erlenmeyer (*Zeitschr. f. Chem.* [2] v. 175) has, however, shown that it melts at 125° to 126° , and this result has been confirmed by a subsequent observation of Fehling.

Succinimide is isomeric with cyano-propionic acid, the difference of constitution of the two being represented by Erlenmeyer as follows:

Cyanopropionic acid.

Succinimide.

The formation of succinimide from succinic anhydride and ammonia may then be represented by the following equation:

Succinimide dissolves in acetone, and crystallises therefrom by slow evaporation in rhombic octohedrons, P, modified by the faces $\frac{1}{2}\text{P}$, $\frac{1}{3}\text{P}$, 0P , and $\frac{1}{2}\text{P}\infty$. Boiled with a slight excess of silver oxide and water, it is converted into silver-succinimide, $\text{C}^4\text{H}^4\text{O}^2\text{N}\text{Ag}$, which separates in crystals from the hot filtrate (Bunge, *Ann. Ch. Pharm. Suppl.* vii. 128).

Iodosuccinimide, $C^4H^4O^2.NI$, is formed by adding silver-succinimide in fine powder to a solution of iodine in alcohol or anhydrous ether, or better in pure and dry acetone, and crystallises from the filtered liquid by spontaneous evaporation in quadratic prisms, ∞P , acuminate at one end by P, and at the other by P and 2P. Axes $a : c = 1 : 0.8733$. It decomposes and turns yellow at 100° , and at 135° is converted into a brown liquid with sublimation of iodine. It dissolves very easily in acetone and in water, less easily in alcohol, still less in ether. Treated in aqueous solution with hydrogen sulphide, it yields hydriodic acid and succinimide. Boiled with silver oxide it yields silver-succinimide and silver-iodide (doubtless also iodate). It is also converted into succinimide by the action of silver nitrite on its solution in acetone (Bunge).

SUCCINYL-PHENOL, $C^4H^4O^2(OC^2H^5)^2$, is produced by heating 4 pts. succinyl chloride and 5 pts. phenol to 100° in a flask provided with a reversed condenser. The crystalline product dissolves easily in boiling absolute alcohol, and the filtered solution on cooling deposits it in nacreous laminae. It is insoluble in water, soluble in ether, carbon bisulphide, and benzol, melts at 118° , and distils without decomposition at 330° . Bromine acts violently upon it, producing tribromosuccinyl-phenol, as a chalky crystalline powder, which dissolves only in a large quantity of boiling alcohol, and separates therefrom in soft white needles; it is decomposed by boiling alcoholic potash, yielding succinic acid and dibromophenol. Succinyl-phenol is not attacked by acetyl chloride even at 100° (Weselsky, *Deut. chem. Ges. Ber.* ii. 518; *Zeitschr. f. Chem.* [2] vi. 60).

SUGARS. 1. *Cane-sugar* or *Saccharose*.—W. Stein (*J. pr. Chem.* cvii. 444; *Zeitschr. f. Chem.* [2] vi. 286) has obtained from madder-root 8 p. c. of crystallised cane-sugar, and is of opinion that the total quantity of this sugar in the root amounts to 14 to 15 p. c., but that part of it is uncrystallisable (? inverted sugar).

On the optical method of estimating sugar, see E. Mulder, *Schrik. Onderz.* iii. [2] 169; *Jahresb.* 1863, p. 709;—Teirich, *Zeitschr. anal. Chem.* iii. 501;—H. Wild, *ibid.* 226, 498;—Scheibler, *ibid.* 509;—Gerlach, *Dingl. pol. J.* clxxii. 31, 286;—Scheibler, *Zeitschr. anal. Chem.* v. 240; vi. 466;—Anders, *Dingl.* clxxix. 71; *Bull. Soc. Chim.* [2] vi. 429;—Landolt, *Dingl.* clxxxvii. 251; *Zeitschr. anal. Chem.* vii. 1.

Dubrunfaut (*Dingl.* clxxxv. 231; *Jahresb.* 1867, p. 932) determines the quantity of crystallisable sugar in beet-sugar and cane-sugar by means of the polariscope, and the quantity of molasses by the alkalimetric value of the ash, this latter method being founded on the observation that molasses of similar origin yield by incineration residues containing nearly equal quantities of carbonates. A modification of this method adopted in sugar-works consists in incinerating the molasses with addition of sulphuric acid, and weighing the sulphates thus obtained.

A table for the rapid approximate determination of the proportion of sugar in a solution from its specific gravity is given by E. Anthon (*Dingl.* clxxxix. 135; *Jahresb.* 1868, p. 957).

Sp. gr.	Percentage-composition of Solution saturated at 17.5°		
	Sugar	Other Substances	Water
1.3300	66.66	0	33.34
1.3322	64.85	2.66	32.49
1.3384	63.70	5.29	31.01
1.3446	62.65	7.76	29.68
1.3509	61.42	10.13	28.45
1.3572	60.28	12.48	27.24
1.3636	59.14	14.67	26.19
1.3700	58.00	16.82	25.18
1.3764	56.85	18.87	24.28
1.3829	55.70	20.77	25.53
1.3894	54.56	22.59	22.85
1.3959	53.42	24.36	22.22
1.4025	52.28	25.98	21.74
1.4092	51.14	27.56	21.30
1.4059	50.00	29.00	21.00

On the estimation of sugar in wine, see Stahlschmidt (*Zeitschr. f. Chem.* [2] iv. 720); on the determination of sugar and alcohol in liqueurs, Pohl (*Dingl. pol. J.* clxxxiii. 163; *Zeitschr. anal. Chem.* vi. 270; *Jahresb.* 1867, p. 874).

The crystallisation of sugar is very much hindered by the presence of certain salts, especially of sodium chloride, and in a less degree of potassium chloride; potassium nitrate appears to have no influence (Payen, *Compt. rend.* lxx. 692; see also *Chem. Soc. J.* [2] vii. 124).

According to Sostmann (*Zeitschr. f. Chem.* [2] ii. 254, 480; *Jahresb.* 1866, p. 666), cane-sugar is not permanently altered by heating to 100° with solution of caustic potash or soda, the liquid after neutralisation with acetic acid exhibiting the same optical rotatory power as a pure sugar-solution containing the same percentage of sugar. The compounds of sugar with the alkalis are separated from the aqueous solution by alcohol or ether as oily masses. The sodium-compound may be dried, but the potassium-compound and the compound of sugar with potassium carbonate remain viscid and transparent, even after prolonged drying at 100° in a stream of air free from carbonic acid. The diminution of the optical power of sugar by the presence of alkalis or alkaline carbonates is not—as found for the alkaline earths by Bodenbender (*Jahresb.* 1865, p. 601)—proportional to the quantity of the base; it appears to depend upon the concentration of the sugar-solution. All these compounds are decomposed by carbonic acid, the sugar completely recovering its rotatory power, which is not affected by the alkaline bicarbonate produced.

According to Pelouze (*Compt. rend.* lix. 1073; *Jahresb.* 1864, p. 572), a solution containing 6 to 12 pts. lime to 1 pt. sugar deposits on addition of alcohol a *bibasic calcium succrate*, $C^{12}H^{22}O^{11}.2CaO$, which is resolved by boiling into the *tribasic salt* $(C^{12}H^{22}O^{11}.3CaO$ and free sugar. See also Brown a. Loiseau (*Compt. rend.* lx. 164; *Jahresb.* 1865, p. 600). A *triprismatic salt*, $C^{12}H^{16}O^{11}Pb^3$, is precipitated on adding potash or soda to a sugar-solution mixed with neutral lead acetate. It is insoluble in cold water, very slightly soluble in boiling water, very easily in sugar-water, the solution on standing depositing the whole of the lead in the form of the diprismatic compound $C^{12}H^{16}O^{11}Pb^2$ (Boivin a. Loiseau).

Jacobsthal (*Zeitschr. f. Chem.* [2] v. 150) has determined the solubility of certain sparingly soluble salts, namely carbonate, sulphate, oxalate, citrate, and basic phosphate of calcium, and carbonate of magnesium in sugar-solutions of various strengths: he finds that all these salts, excepting the magnesium carbonate, are less soluble in sugar-solutions than in pure water, the quantity of salt dissolved being less as the strength of the sugar-solution is greater.

The solubility of several metallic oxides in solutions of calcium succrate containing free sugar has been determined by Bodenbender (*Zeitschr. f. Chem.* [2] ii. 124; *Jahresb.* 1865, p. 600).

On the influence of sugar on the precipitation of metallic oxides by alkalis, see ANALYSIS, INORGANIC (pp. 125, 126).

The action of water and of various saline solutions on cane-sugar has been studied by Chasen (*J. pr. Chem.* ciii. 449; *Zeitschr. f. Chem.* [2] iv. 604), with the following results: 1. Cane-sugar in dilute aqueous solution in glasses covered with paper is gradually converted into glucose at ordinary temperatures, *before the formation of fungi takes place on the surface*; but no alteration of the sugar takes place when its dilute solution is boiled for several hours immediately after preparation.—2. The formation of glucose is prevented by gypsum, by a mixture of gypsum and sal-ammoniac, and by nitro; retarded by magnesium sulphate.—3. When a sugar-solution mixed with gypsum, potassium nitrate, or magnesium sulphate, after standing for several days at 70° F., is heated for a few hours only, a considerable quantity of glucose is formed.—4. When a sugar-solution is mixed with gypsum and sal-ammoniac and heated, ammonia is given off and the solution turns acid. In presence of this saline mixture glucose is formed, even when the sugar-solution is recently prepared.—5. In all other cases no acid reaction of the liquid was observed, and the transformation must be ascribed wholly to the action of the water.—6. Whether the product formed was actually grape-sugar or some other kind of sugar which reduces potassio-cupric tartrate, was not determined.

When *chlorine* is passed for some time into a solution of cane-sugar, there is formed, together with other uncrystallisable products, a new acid free from chlorine, the barium salt of which may be obtained in the crystalline state by saturating the solution with baryta-water (after removing the hydrochloric acid by mercurous oxide) and adding alcohol in sufficient quantity to produce turbidity.

With *acetic anhydride* cane-sugar yields the same product as glucose (p. 1044).

On saline compounds of cane-sugar see Gill (*Chem. Soc. J.* [2] ix. 269).

2. Glucose. $C^6H^{12}O^6$.—According to Dubrunfaut (*Compt. rend.* lxxiii. 546), this, or a similar sugar capable of reducing cupric oxide, exists to the amount of 0.2 to 1.2 p. c. in most of the sugars, both raw and refined, prepared from beet.

The specific rotatory power of dextroglucose has been determined by Hoppe-Seyler by means of a solution of sugar from urine, purified by repeated crystallisation. For the following spectral lines the specific rotatory powers are:

C	D	E	δ	F
42.45°	53.45°	67.9°	71.8°	81.3° (?)

As the rotation found for the line D agrees with that found by lamp-light for the transition tint, the value of the rotation for this tint must be taken, in all calculations of the amount of glucose in solutions founded on their optically rotatory power, as $[\alpha]_D = 53.5^\circ$. The value 56° found by Berthelot is inexact, inasmuch as all natural varieties of dextroglucose (except urine-sugar), and all artificial varieties, contain either starch or fruit-sugar, and the solubility of dextrin in absolute alcohol renders it impossible to separate this substance completely from glucose.

Reichardt (ii. 966) by treating glucose in alkaline solution with cupric oxide obtained an acid which he designated as *gummy acid*, and represented by the formula $C^6H^{10}O^6$. Claus (*Ann. Ch. Pharm.* cxlvii. 114; *Jahresb.* 1868, p. 760) has shown that this acid is tartaric acid, $C^4H^4O^6$ (v. 698).

When glucose is boiled with a mixture of pentachloride and oxychloride of phosphorus, and water, amorphous colourless flocks separate which gradually dissolve in the water: this seems to indicate the formation of an anhydride or chlorinated derivative of glucose (Baeyer, *Zeitschr. f. Chem.* [2] v. 345).

Nitroglucose.—Glucose is not so easily nitrated as cellulose, requiring stronger acids and a lower temperature. To prepare nitroglucose, the pulverised sugar is stirred up to a thin paste with 2 pts. fuming sulphuric acid, 2 pts. ordinary sulphuric acid, and 2 pts. nitric acid of sp. gr. 1.5. It then separates, after a while in pasty lumps, which must be immediately removed from the liquid and freed from acid by kneading them with water, to prevent decomposition by the further action; or, better, the crude mass may be dissolved in a mixture of alcohol and ether, and the solution poured, with brisk and constant stirring, into cold water. Nitroglucose is a white, shining body, which when immersed in water (the best way of keeping it) gradually hardens, sometimes to an amorphous, sometimes to a granulo-crystalline mass. It appears to be quite insoluble in water, but dissolves in a mixture of alcohol and ether as easily as sugar in water. It detonates but slightly and burns with a faint flame when set on fire (Carey Lea, *Sill. Am. J.* [2] xlv. 381).

Acetyl-glucose.—1 pt. of glucose heated in an open vessel with $2\frac{1}{2}$ pts. acetic anhydride to the boiling point of the latter is rapidly attacked, yielding diacetyl-glucose, $C^6H^{10}(C^2H^3O)^2O^6$, which when purified is a solid colourless body easily soluble in water, alcohol, ether, and acetic acid, having a very bitter taste, and melting below 100° . Heated to 140° with about twice its weight of acetic anhydride, it is converted into triacetyl-glucose, $C^6H^8(C^2H^3O)^3O^6$, which is also solid, sparingly soluble in pure water, but easily soluble in water containing acetic acid, also in alcohol and ether. Lastly, when this compound is heated to 160° for four hours with a large excess of acetic anhydride, a saturated compound is formed similar to the preceding, but insoluble in water containing acetic acid. On pouring the liquid into water a viscid precipitate is formed, which is obtained pure by washing with water, solution in alcohol, treatment with animal charcoal, and evaporation of the filtered solution. Its analysis leads to the formula of octaacetyl-saccharose, $C^{18}H^{22}(C^2H^3O)^8O^{11}$; perhaps however it may consist of tetraacetyl-glucose, $C^6H^8(C^2H^3O)^4O^6$.

Cane-sugar and milk-sugar heated with acetic anhydride also yield saturated derivatives apparently identical with that obtained from glucose (Schützenberger, *Compt. rend.* lxxiii. 264; *Zeitschr. f. Chem.* [2] v. 264).

A mixture of triacetyl-glucose and sodium-saligenin, heated with benzol to the boiling point of the latter, yields acetyl-saliretin, $C^{14}H^{14}(C^2H^3O)^2O^2$, together with sodium gluconate or a similar salt, sodium acetate, and lastly a small quantity of a product which is precipitated by lead acetate, and when boiled with dilute sulphuric acid is resolved into sugar and saliretin. Similar results are obtained with diacetyl-glucose. Larger quantities of acetyl-saliretin are produced by heating the lead-compound of saligenin with acetyl-glucose (Schützenberger, *Compt. rend.* lxi. 350; *Zeitschr. f. Chem.* [2] v. 632).

An aqueous solution of acetyl-saccharose heated with the lead-compound of *rhonnetin* yields a glucoside which is precipitated by the lead acetate formed at the same time, and may be obtained in the free state by decomposing the yellow

precipitate with hydrogen sulphide. By boiling with dilute acids it is resolved into rhamnetin and glucose (Schützenberger).

3. Laevulose. Inverted Sugar. This kind of sugar exists, together with saccharose, in the sugar-cane, especially in the upper parts of the stem which are still enveloped by the green leaves, and thereby protected from light; in these it sometimes amounts to $\frac{1}{2}$ of the quantity of saccharose. As the leaves dry up, and the upper part of the stem becomes exposed to light, the uncrystallisable sugar gradually becomes converted into crystallisable saccharose; in the lower part of the stem the proportion of uncrystallisable to crystallisable sugar does not exceed $\frac{1}{5}$ to $\frac{1}{10}$. It is probable therefore that the crystallisable sugar of the cane is only a secondary product formed by the action of light on the fruit-sugar originally existing in the stem (Icory, *Ann. Ch. Phys.* [4] v. 350; *Jahresb.* 1865, p. 819).

Gräber (*N. Jahrb. Pharm.* xxix. 294) has made a series of experiments on the rate of conversion of cane-sugar into grape-sugar (more correctly inverted sugar) by dilute tartaric acid in presence of alcohol. In solutions containing from 6.8 to 10 pts. of tartaric acid per thousand, the transformation takes place very slowly at ordinary, more quickly at higher temperatures, e.g. at 45°. In an alcoholic mixture of 10 pts. alcohol, 10 pts. cane-sugar, 1 pt. tartaric acid, and 79 pts. water, 93 p. c. of the sugar was transformed into inverted sugar in 14 weeks (at about 18°). In wine the transformation takes place much more quickly; nevertheless wine loses the power of rapidly converting cane-sugar into inverted sugar when heated to 60°–70°.

On the nature of inverted sugar, see Maumené a. Dubrunfaut (*Compt. rend.* lxi. 1008, 1151, 1242, 1366; *Zeitschr. f. Chem.* [2] vi. 149).

4. Galactose. Pasteur, by treating milk-sugar with dilute acids, obtained a sugar thus designated, having the composition $C^6H^{12}O^6$ (iii. 1023). According to Fudakowski (*Zeitschr. f. Chem.* [2] iii. 32; *Bull. Soc. Chim.* [2] vi. 238), milk-sugar boiled with very dilute sulphuric acid yields two kinds of sugar, one of which, *a*, crystallises from the syrup freed from the acid and from lime, on addition of alcohol, while the other, *b*, separates after some time from the mother-liquor. The sugar *a* forms, after recrystallisation, small rectangular prisms with two end-faces; the sugar *b* crystallises in the six-sided tables observed by Pasteur. Both are fermentable, dextrogyrate, moderately soluble in water, but differ by their solubility in alcohol, the tabular sugar *b* being much the more soluble of the two; it appears also to have a sweeter taste and to be more easily fermentable. The specific rotatory powers of the solutions after warming or long standing are as follows:

	C	D	E
For the sugar <i>a</i> . . .	73.66°	92.83°	112.02°
For the sugar <i>b</i> . . .	50.37°	62.83°	83.03°

Both these sugars, like grape-sugar or milk-sugar, exhibit, immediately after solution in cold water, a greater rotatory power than after standing or warming.

5. Pectin-sugar or Pectinose. $C^6H^{12}O^6$.—See PECTOUS SUBSTANCES (p. 903).

6. Sugar from Carminic Acid. This sugar, obtained, together with carminic-red, by boiling carminic acid with dilute sulphuric acid (p. 414), has the composition $C^6H^{12}O^6$ when dried at 50°, $C^6H^{12}O^6$ at 100°. It is a honey-yellow, amorphous, hygroscopic mass, having a faint odour of caramel and a bitterish taste; dissolves very slightly in alcohol; easily reduces cupric oxide in alkaline solution; exhibits, even in very small quantity, Pettenkofer's bile reaction; is unfermentable and optically inactive (Hlasiwetz a. Grabowski).

7. Rhamnegin-sugar. A kind of sugar isomeric with mannite, $C^6H^{14}O^6$, obtained, together with rhamnetin, by boiling rhamnegin with dilute sulphuric acid:

It is uncrystallisable and very sweet, dries up in a vacuum to a soft, amorphous, very hygroscopic, deliquescent mass, turns brown at 100°, and gives off 1 mol. water, leaving a residue which has the composition $C^6H^{10}O^5$. It is dextrogyrate: $[\alpha]$ about = 26° (Schützenberger, *Compt. rend.* lxxvii. 176).

8. Dambonite and Dambosc. Dambonite, $C^6H^{10}O^6$, is a crystallisable sugar existing ready-formed in Gaboon caoutchouc; and dambosc, $C^6H^{10}O^6$ or $C^6H^{12}O^6$, is formed from it, together with methyl iodide, by the action of hydriodic acid (p. 541).

SUGAR-CANE. Elaborate investigations on the sugar-cane, the extraction of the juice from it, the composition of the juice, and the changes to which it is liable, have been made by Icory (*Ann. Ch. Phys.* [4] v. 350; abstr. *Jahresb.* 1865, p. 818).

SULPHACETIC ACID, $\text{CH}_2\begin{pmatrix} \text{SO}^2\text{OH} \\ \text{COOH} \end{pmatrix}$, is formed, as potassium salt, by boiling monochloroacetic acid with a solution of potassium sulphate (Strecker, *Zeitschr. f. Chem.* [2] iv. 214):

SULPHACETONE, $\text{C}_2\text{H}_4\text{S}$, or rather the polymeric compound $\text{C}_6\text{H}_8\text{S}_2$, is formed by the action of 1 mol. phosphorus trisulphide on 6 mol. acetone, the action beginning at ordinary temperatures, and being completed at the heat of the water-bath. The upper layer of liquid thereby produced yields sulphacetone by fractional distillation, as a yellowish oil boiling between 183° and 185° (corr.), and having a vapour-density = 5.0787 (calculation for $\text{C}_6\text{H}_8\text{S}_2$ gives 5.114). It irritates the skin, and its vapour attacks the eyes very strongly (Wislicenus, *Zeitschr. f. Chem.* [2] v. 324).

SULPHAMMONIC ACIDS (Claus a. Koch, *Zeitschr. f. Chem.* [2] v. 684).—The potassium salts of these acids—Frémy's *sulphazotised acids* (v. 482)—are produced by the mutual action of nitrite and sulphite of potassium. When neutral solutions of these two salts are mixed together, the mixture becomes turbid after a while, and deposits slender needle-shaped crystals, the liquid at the same time acquiring an alkaline reaction. The crystals sometimes consist of a single salt, sometimes of a mixture of several, according to the proportions of the sulphite and nitrite added and the concentration of the solution. When the sulphite is in considerable excess, only one salt is formed, viz. potassium tetrasulphammonate, $\text{K}^4\text{HNS}^2\text{O}^{12} + 3\text{H}_2\text{O}$:

This salt crystallises in needles. It is very unstable, cannot be kept long even in the dry state, and decomposes in a few minutes when washed on a filter with water, the water acquiring an acid reaction. Under an alkaline solution it is more permanent, but even then it decomposes quickly when heated even to temperatures short of the boiling point. By addition of acids the decomposition is still further accelerated; but complete decomposition, resulting in the formation, not of another sulphazotised acid, but of sulphuric acid, takes place only after prolonged boiling with dilute acids, or after heating with a concentrated acid. In neither of these cases is any oxide of nitrogen reproduced, but the whole of the nitrogen passes into the form of ammonia. The hydrated salt, when quickly heated, suffers complete decomposition, leaving potassium sulphate; the anhydrous salt heated above 200° gives off ammonium sulphate, nitrogen, and sulphurous oxide; by dry distillation with soda-lime all the nitrogen is eliminated as ammonia.

In the cases above mentioned of spontaneous decomposition of the dried substance, decomposition by prolonged contact with water, or by boiling with dilute potash, 1 mol. of the tetrasulphammonate is always resolved into 1 mol. of acid potassium sulphate, and 1 mol. of potassium trisulphammonate, $\text{K}^3\text{H}^2\text{NS}^2\text{O}^9$ (Frémy's sulphammonate). In the decomposition by water the reaction is

in boiling with potash, neutral potassium sulphate is of course obtained instead of the acid sulphate. The best way of preparing this salt is to mix 3 eq. of potassium sulphite with 1 eq. of the nitrite, and after about an hour, when the tetrasulphammonate has separated, and the alkaline reaction has become strong, to warm the mixture in the water-bath. The whole of the crystals then generally dissolve; if not, a little water must be added till a clear solution is formed, and from this the trisulphammonate separates in fine crystals on cooling. Pure potassium trisulphammonate, when decomposed at a high temperature, yields (contrary to Frémy's statement) not a trace of any oxide of nitrogen, the products of its decomposition being potassium sulphate, sulphuric acid, ammonium sulphate, and sulphurous acid. Strong sulphuric acid and nitric acid act on it but slowly in the cold, and when heated dissolve it without evolution of gas, forming the sulphates of potassium and ammonium. A solution of the trisulphammonate in water at 30° – 40° forms with basic lead acetate a thick white precipitate, which, however, is not of constant composition. It does not appear to form an insoluble salt by double decomposition with any other metallic salt.

The trisulphammonate boiled with pure, or, better, with slightly acidulated water, splits up into acid sulphate and disulphammonate of potassium:

This last salt, identical with Frémy's sulphamidate, separates on cooling from a hot aqueous solution in very characteristic forms; a drop of the hot solution left to cool under the microscope exhibits at first regular six-sided tables, changing afterwards to six-sided prisms having the character of augite crystals. They are anhydrous,

1048 SULPHOBENZENE—SULPHOCARBAMIC ACID.

and may be heated to 150° without alteration. It is scarcely attacked by strong sulphuric acid in the cold, but dissolves in it when heated, and is converted into the sulphates of potassium and ammonium. It is very sparingly soluble in cold water, and instantly crystallises from a hot aqueous solution on the addition of a few drops of potash. From concentrated, hot-saturated solutions, neutral lead acetate throws down a white precipitate; basic lead acetate also from very dilute solutions.

The other sulphazotised salts, designated by Frémy as *sulphazates*, *sulphazotates*, &c., have not been obtained pure, but they appear to differ essentially in constitution from the sulphammonates, inasmuch as when boiled with water, or heated in the air, or with sulphuric or nitric acid, they give off nitrogen dioxide, and when heated with soda-lime, give off only part of their nitrogen as ammonia, or in most cases do not yield any ammonia.

See further Claus (*Deut. chem. Ges. Ber.* iv. 186, 504; *Chem. Soc. J.* [2] ix. 307, 659).

SULPHOBENZENE or SULPHOBENZIDE. See BENZENE, DERIVATIVES OF (p. 276).

SULPHOBENZOLAMIDE. $C^6H^5NSO^2 = NH^2(SO^2C^6H^5)$.—This compound, which Stenhouse obtained by heating ammonium phenylsulphite to 200° (v. 489), is also produced by the action of ammonia on sulphobenzol-bromide or phenylsulphurous bromide, $C^6H^5SO^2Br$. It is nearly insoluble in cold water, more soluble in hot ammoniacal water, easily soluble in hot alcohol and in ether, and crystallises in large nacreous laminae melting at 149° (Otto a. Ostrop, *Ann. Ch. Pharm.* cxli, 365; *Jahresh.* 1866, p. 570).

SULPHOBENZOLIC ACID. See BENZENE, DERIVATIVES OF (p. 273).

SULPHOCARBAMIC ACID. $CH^3NS^2 = CS\begin{Bmatrix} NH^2 \\ SH \end{Bmatrix}$ (Mulder a. Wefers Bettinck, *J. pr. Chem.* ciii. 178; *Zeitschr. f. Chem.* [2] iv. 376).—In the ordinary mode of preparing ammonium sulphocarbamate (v. 490), the sulphocarbonate is likewise formed more or less abundantly at the beginning of the reaction; but if the ammonia-gas from 150 pts. of sal-ammoniac be passed into 600 pts. of alcohol of 95 p. c., 96 pts. of bisulphide then added, and the solution left to crystallise, the crystals deposited consist wholly of sulphocarbamate. On gradually adding hydrochloric acid to a concentrated solution of ammonium sulphocarbamate, sulphocarbamic acid is sometimes deposited in colourless needle-shaped crystals, especially if the solution be slightly cooled.

Sulphocarbamic acid is solid at ordinary temperatures, very soluble in water, alcohol, and ether; the solutions have an acid reaction. The acid is rather unstable; its alcoholic solution gradually deposits crystals of ammonium sulphocarbamate, and on heating it, carbon bisulphide is given off, and ammonium sulphocarbamate (insoluble in alcohol) is immediately formed:

The same decomposition takes place when the aqueous solution is heated; on evaporating it, a large quantity of ammonium sulphocyanate is formed:

On *Sulphocarbamate of Acetonine*, see ACETONINE (p. 29).

Action of Iodine on Sulphocarbamates.—When a strong alcoholic solution of iodine is poured into an alcoholic solution of ammonium sulphocarbamate, the colour of the iodine disappears, sulphur is deposited, and ethyl-sulphocarbimide is formed, together with ethylamine:

(Hofmann, *Zeitschr. f. Chem.* [2] v. 671).

Action of Aldehydes.—When an alcoholic or aqueous solution of acetic aldehyde is agitated with ammonium sulphocarbamate, carbothialdine is produced, which, therefore, has the composition of *diethylidenammonium sulphocarbamate*:

In the decomposition of carbethalidine, aldehyde is always reproduced. The homologous compound, *diethylidenammonium sulphocarbamate*, $\text{CS}\left\{\begin{smallmatrix} \text{NH}^2 \\ \text{SN}(\text{C}^2\text{H}^5)_2 \end{smallmatrix}\right.$, is obtained by agitating ammonium sulphocarbamate with valeral in alcoholic solution, and pouring the filtered liquid into water, as a colourless flocculent precipitate, which after washing with water, pressing between paper, and drying in a vacuum, forms a shining crystalline mass. Heated with ferric chloride it gives the sulphocyanogen reaction. *Diallylidenammonium sulphocarbamate*, $\text{CS}\left\{\begin{smallmatrix} \text{NH}^2 \\ \text{SN}(\text{C}^3\text{H}_7)_2 \end{smallmatrix}\right.$ obtained by agitating acrolein with ammonium sulphocarbamate in aqueous solution in a cooled vessel, is colourless, apparently amorphous, insoluble in water and alcohol; gives the sulphocyanogen reaction when heated with ferric chloride (Mulder a. Bettinck).

Ethyl sulphocarbamate, $\text{CS}\left\{\begin{smallmatrix} \text{NH}^2 \\ \text{SC}^2\text{H}_5 \end{smallmatrix}\right.$, is formed by the action of hydrogen sulphide on ethyl sulphocyanate. It is converted by the fixed alkalis into ethyl sulphide and metallic sulphocyanate; by ammonia into ethyl sulphide and sulphocarbamide, isomeric with ammonium sulphocyanate. A mixture of ethyl sulphocarbamate and ethyl iodide solidifies to a crystalline mass, apparently consisting of a compound of the two in equivalent proportions. The iodides of methyl and amyl, as well as the bromides of the same radicles, react in the same manner with the sulphocarbamates of ethyl and its homologues (Jeanjean, *Jahresb.* 1866, p. 501).

Ethyl-sulphocarbamic Acid. $\text{C}^2\text{H}^5\text{NS}^2 = \text{CS}\left\{\begin{smallmatrix} \text{NH}(\text{C}^2\text{H}^5) \\ \text{SH} \end{smallmatrix}\right.$.—An alcoholic solution of ethylamine mixed with carbon bisulphide becomes hot, loses its alkaline reaction, and, if sufficiently concentrated, deposits six-sided tables of ethylsulphocarbamate of ethyl-ammonium:

This salt melts at 103° , and partly sublimes without decomposition when gently heated. It is soluble in water and easily soluble in alcohol. With caustic soda it gives off ethylamine, and is converted into sodium ethylsulphocarbamate, which, on addition of hydrochloric acid, yields ethylsulphocarbamic acid in oily drops floating on the surface, and solidifying after a while to fatty crystals. On adding more hydrochloric acid, the oily drops dissolve, with evolution of carbon bisulphide, and nothing but ethylamine hydrochloride remains in solution. Ethyl-ammonium ethylsulphocarbamate is decomposed when heated to 100° , and more easily when its alcoholic solution is heated under pressure to 110° – 120° , giving off hydrogen sulphide, and leaving diethylsulphocarbimide, in the form of an oily liquid, which soon solidifies to crystals:

Ethylsulphocarbamic acid in the free state resolves itself into its components, ethylamine and carbon bisulphide; but its metallic salts, especially in presence of excess of another metallic salt (*e.g.* silver nitrate or mercuric chloride), are easily resolved into ethyl-sulphocarbamide and a metallic sulphhydrate (p. 1050):

The corresponding *methyl*- and *amyl*-compounds are obtained by similar processes, and exhibit similar reactions (Hofmann, *Zeitschr. f. Chem.* [2] iv. 686; *Jahresb.* 1868, p. 653).

Ethylic Ethyl-oxy-sulphocarbamate, *Ethyl-xanthamide*, or *Semi-sulphuretted Ethyl-urethane*, $\text{CS}\left\{\begin{smallmatrix} \text{NH}(\text{C}^2\text{H}^5) \\ \text{OC}^2\text{H}^5 \end{smallmatrix}\right.$, is produced by direct combination of ethyl-sulphocarbimide, $\text{N}(\text{CS})(\text{C}^2\text{H}^5)$, and ethyl-alcohol, $\text{HO}(\text{C}^2\text{H}^5)$, when the two are heated together to 110° in a sealed tube for several hours, and is precipitated on mixing the resulting liquid with water, as an oil having a somewhat unpleasant alliaceous odour, and boiling, after purification, at 204° – 208° . Under the influence of water, and especially in presence of acids or alkalis, it is resolved into alcohol, carbon dioxide, hydrogen sulphide, and ethylamine. With strong sulphuric acid, carbon oxy-sulphide is formed instead of carbon dioxide and hydrogen sulphide. The above-described compound is likewise produced by the action of alcoholic soda-solution on ethyl-sulphocarbimide; but the corresponding sodium salt is always produced at the same time by the action of the sodium hydrate, and ultimately part

of the ethylsulphocarbimide is completely decomposed, with formation of sodium carbonate, sodium sulphide, and ethylamine.

A compound isomeric with the preceding, and differing from it only in the relative position of the sulphur and oxygen atoms, is produced by heating ethylic mercaptan with ethyl cyanate to 120°. This body, $\text{CO}\left\{\begin{smallmatrix} \text{NH}(\text{C}^2\text{H}^5) \\ \text{SC}^2\text{H}^5 \end{smallmatrix}\right.$, is heavier than water, has the same odour as the preceding, and likewise boils at 204°–208°. By the action of water, especially in presence of acids or alkalis, it is resolved into mercaptan, carbon dioxide, and ethylamine.

Ethylic Ethylsulphocarbamate, Diethyl-xanthamide, or Sulphuretted Ethyl-urethane, $\text{CS}\left\{\begin{smallmatrix} \text{NH}(\text{C}^2\text{H}^5) \\ \text{SC}^2\text{H}^5 \end{smallmatrix}\right.$, is produced by digesting mercaptan with ethyl-sulphocarbimide to 120° for several hours. It is heavier than water, and does not exhibit the odour of either of its constituents. It is decomposed by distillation (Hofmann, *Zeitschr. f. Chem.* [2] v. 268).

Ethylic Allyl-oxy-sulphocarbamate, $\text{CS}\left\{\begin{smallmatrix} \text{NH}(\text{C}^3\text{H}^7) \\ \text{OC}^3\text{H}^7 \end{smallmatrix}\right.$, obtained by digesting an alcoholic solution of mustard-oil for some hours to a temperature a little above the boiling point of water, and precipitating with water, is an oil having an alliaceous odour, somewhat heavier than water, and boiling at 210°–215°. It is the same compound that Will n. Körner obtained (v. 518) by treating mustard-oil with alcoholic potash, and to which they assigned the formula $\text{C}^1\text{H}^{12}\text{N}^2\text{S}^2\text{O}^2$ (Hofmann).

Ethylic Phenyl-oxy-sulphocarbamate, $\text{CS}\left\{\begin{smallmatrix} \text{NH}(\text{C}^6\text{H}^5) \\ \text{OC}^6\text{H}^5 \end{smallmatrix}\right.$, is produced in like manner by heating phenylsulphocarbimide with alcohol to 110°–115°. The resulting solution poured into water solidifies to a crystalline mass, which may be purified by washing with water and recrystallisation from alcohol. It is resolved by distillation into its constituents. The same compound may be obtained, though less easily, from diphenylsulphocarbimide, which is the starting point for the preparation of phenyl-sulphocarbimide (p. 1056).

Ethylic Phenylsulphocarbamate or Sulphuretted Phenyl-urethane, $\text{CS}\left\{\begin{smallmatrix} \text{NH}(\text{C}^6\text{H}^5) \\ \text{SC}^6\text{H}^5 \end{smallmatrix}\right.$, is produced by the combination of mercaptan with phenyl-sulphocarbimide. It is a finely crystallised compound, insoluble in water, soluble in alcohol and ether, melting at 56° (Hofmann).

SULPHOCARBAMIDES (Hofmann, *Zeitschr. f. Chem.* [2] iv. 201, 686; vi. 157).—*Ethyl-sulphocarbimide*, $\text{N}^2\left\{\begin{smallmatrix} \text{CS} \\ \text{C}^2\text{H}^5 \\ \text{H}^3 \end{smallmatrix}\right.$, is formed by direct addition of ammonia in alcoholic solution to ethyl-sulphocarbimide, $\text{N}(\text{CS})(\text{C}^2\text{H}^5)$ (p. 1055), and solidifies to a crystalline mass which by recrystallisation from hot water is converted into beautiful needles. It melts at 100°, is moderately soluble in water and more easily in alcohol, dissolves also in hydrochloric acid, and forms a yellow precipitate with platinic chloride. It is easily desulphurised, either in aqueous or in alcoholic solution, by lead oxide or mercuric oxide; and on evaporating the resulting solution over the water-bath, there remains a syrupy liquid which solidifies after some time to a network of crystals having a strong alkaline reaction. It is probable, however, that an intermediate product is first formed, as the liquid, especially if diluted, does not exhibit alkaline reaction immediately after desulphuration. The white crystals, although very soluble, must be recrystallised either from water or from alcohol. Their solution in the smallest possible quantity of hydrochloric acid gives with platinic chloride a crystalline platinum salt consisting of $\text{C}^2\text{H}^5(\text{C}^2\text{H}^5)\text{N}^2 \cdot 2\text{HCl} \cdot \text{PtCl}_4$. Probably the first product of the desulphuration is ethylcyanamide: $\text{N}^2(\text{CS})\text{H}^3(\text{C}^2\text{H}^5) - \text{H}^2\text{S} = \text{N}(\text{CN})(\text{C}^2\text{H}^5)\text{H}$; and three molecules of this compound then unite to form the biacid base: $3\text{N}(\text{CN})(\text{C}^2\text{H}^5)\text{H} = \text{C}^2\text{H}^3(\text{C}^2\text{H}^5)^3\text{N}^6$, which may be regarded as melamine, $\text{C}^2\text{H}^3\text{N}^6$, having 3 at. hydrogen replaced by ethyl (p. 808).

Diethyl-sulphocarbimide, $\text{N}^2(\text{CS})^2(\text{C}^2\text{H}^5)^2\text{H}^2$, is produced by addition of ethylamine to ethylsulphocarbimide, also with evolution of hydrogen sulphide, by the decomposition of ethylammonium ethyl-sulphocarbamate (p. 1049). It forms crystals melting at 77°, soluble in alcohol, less soluble in water; dissolves also in hydrochloric acid, and gives a yellow crystalline precipitate with platinic chloride. By phosphoric anhydride or anhydrous hydrochloric acid it is resolved into ethylamine and ethylsulphocarbimide. It is not decomposed in aqueous or alcoholic solution by lead oxide, but recently

precipitated mercuric oxide removes the sulphur and replaces it by oxygen, thereby converting the compound into diethylcarbamide (Wurtz's diethyl-urea, i. 754) melting at 107°. By mercuric oxide in presence of ethylamine, diethylsulphocarbamide is converted into triethyl-guanidine:

In presence of ammonia the desulphuration is more complex (Hofmann).

Methyl-ethylsulphocarbamide and *Ethylphenylsulphocarbamide* are formed by addition of methylamine and phenylamine respectively to ethylsulphocarbamide. The methyl-compound forms fine crystals soluble in water, alcohol, and hydrochloric acid, and melting at 145°; the phenyl-compound melts at 97°. The two compounds likewise differ essentially in their relations to solvents, and especially to hydrochloric acid (Hofmann).

Diphenylsulphocarbamide or *Sulphocarbanilide*. $N^2(CS)(C^6H^5)^2H^2$ (i. 754).—This compound treated in alcoholic solution at the boiling heat with iodine also dissolved in alcohol, is resolved into phenylsulphocarbimide, triphenyl-carbotriamine or triphenyl-guanidine, hydriodic acid, and sulphur:

If aniline be added to the solution before the iodine, the products are triphenyl-guanidine, hydriodic acid, and sulphur:

Heated with aniline alone, sulphocarbanilide yields triphenyl-guanidine and hydrogen sulphide:

Diphenylsulphocarbamide is also converted into triphenyl-guanidine by the action of heat and of various desulphurating agents. (See GUANIDINE, pp. 655, 656.) Treated in warm alcoholic solution with zinc and hydrochloric acid, or with sodium-amalgam, it yields aniline, marsh gas, and hydrogen sulphide:

(Merz a. Weith, *Zeitschr. f. Chem.* [2] iv. 612).

Diphenylsulphocarbamide is likewise easily desulphurised by heating it with lead oxide in contact with toluidine. It then yields *diphenyl-tolyl-guanidine*, $N^3[C^1(C^6H^5)^2(C^7H^7)H^2]$, isomeric with rosaniline, which crystallises in beautiful perfectly colourless needles. A solution of diphenylsulphocarbamide in alcoholic ammonia is instantly desulphurised by lead oxide, yielding a base which crystallises in flattened needles and is isomeric or identical with *melaniline* or *carbodiiphenyltri-amine* (iv. 461) (Hofmann, *Zeitschr. f. Chem.* [2] vi. 217):

Diphenylsulphocarbamide heated with *mercuric chloride* yields a fused mass from which water extracts triphenyl-guanidine. From the undissolved portion alcohol extracts diphenylcarbamide, $N^2(CO)(C^6H^5)^2H^2$, probably formed by the action of the solvents on the chlorinated carbamide, $N^2(CCl_2)(C^6H^5)^2H^2$, produced in the first instance (Buff, *Deut. chem. Ges. Ber.* ii. 498; *Zeitschr. f. Chem.* [2] vi. 54).

Ditolylsulphocarbamide or *Sulphocarbotoluide*, $N^2(CS)(C^7H^7)^2H^2$, exhibits reactions precisely similar to those of sulphocarbanilide, being converted by heat and by desulphurising agents, or by heating with toluidine, into tritolyl-carbotriamine or tritolyl-guanidine, $N^3[C^1(C^7H^7)^3H^2]$. In warm alcoholic solution, it is converted by nascent hydrogen into toluidine, but the reaction is slower than with sulphocarbanilide, because the sulphocarbotoluide is less soluble in alcohol (Merz a. Weith). It likewise acts like the phenyl-compound with mercuric chloride, yielding tritolyl-guanidine and ditolyl-carbamide (Buff).

SULPHOCYANIC ACID. CHNS.—On the preparation of this acid, see Hermes (*J. pr. Chem.* xvii. 465).

Sulphocyanic acid is reduced by zinc and excess of dilute sulphuric acid, yielding hydrogen sulphide and methylamine (Merz a. Weith, *Zeitschr. f. Chem.* [2] iv. 611):

According to Hofmann (*ibid.* 689), the products are ammonia, formic sulphaldehyde, CH^3S , hydrocyanic acid, hydrogen sulphide, and methylamine, produced in the following order:

(Hofmann, *ibid.* 688).

Metallic Sulphocyanates. Many metallic sulphocyanates are soluble in ether, and this property may be made available for their preparation. When the brown liquid produced by mixing potassium sulphocyanate with a cobalt salt is shaken up with ether, the ether immediately becomes blue, and deposits on evaporation crystals of cobalt sulphocyanate. The blue colour, which is also produced with alcohol, is destroyed by mercuric chloride and by sodium acetate and hyposulphite. Ethereal solutions of the sulphocyanates of iron, uranium, molybdenum, tungsten, gold, and copper may be obtained in the same manner. The iron salt dissolves so easily that it may be completely extracted by ether from its aqueous solution (Skey, *Chem. News*, xvi. 201).

Ammonium sulphocyanate, $\text{CSN}(\text{NH})^2$, is often present in commercial ammonium sulphate. An alcoholic solution of this salt exhibits in a very high degree the phenomenon of supersaturation. Its concentrated aqueous solution does not dissolve sulphur, but takes up a considerable quantity of iodine, and on heating the resulting liquid, a considerable quantity of persulphocyanogen is deposited. Bromine acts in a similar manner. Chlorine forms no precipitate in the dilute solution, but throws down from the concentrated solution a thick yellow precipitate of persulphocyanogen, agreeing in composition with Vöckel's analyses (iv. 380) (Phipson, *Chem. News*, xviii. 109). Ammonium sulphocyanate melts at 159° (not at 147° , as generally stated), and if kept for some time at the temperature of 170° , is converted into sulphur-urea, $\text{CH}^3\text{N}^2\text{S}$ (J. E. Reynolds, *Chem. Soc. J.* [2] vii. 1).

Chromic Sulphocyanates (Roessler, *Ann. Ch. Pharm.* exl. 185; *Zeitschr. f. Chem.* [2] ii. 615).—*Potassio-chromic sulphocyanate*, $(\text{CNS})^{12}\text{Cr}^6\text{K}^6 + 8\text{H}^2\text{O}$, is obtained by heating the moderately concentrated solutions of 6 pts. potassium sulphocyanate and 5 pts. chrome-alum nearly to the boiling point for about two hours, mixing the cooled liquid with alcohol to precipitate sulphates, evaporating the filtrate, and recrystallising the salt thereby separated from alcohol. It forms nearly black crystals belonging to the quadratic system, ruby-red by transmitted light. It is permanent in the air, gives off its water at 100° , becomes dark-coloured when heated, ruby-red again on cooling; dissolves in 0.72 pts. water, and in 0.94 pts. alcohol. It is not altered by alkaline carbonates or ammonium sulphide even at the boiling heat; but on warming it with soda-ley, or boiling it with ammonia, chromic oxide is separated. Dilute hydrochloric acid decomposes it at the boiling heat; strong hydrochloric acid throws down, together with potassium chloride, a yellow sulphuretted powder, which crystallises from alcohol in needles. By evaporation with hydrochloric acid, the salt is completely decomposed, with formation of chromic chloride and potassium chloride. Nitric acid oxidises it with facility. The salts of the alkaline earth-metals, and those of cadmium, cobalt, nickel, zinc, manganese, and iron, are precipitated by potassio-chromic sulphocyanate. Cupric sulphate changes its wine-red colour to violet-blue, and on standing or warming forms a brown precipitate containing copper. Mercuric chloride forms a red precipitate which agglomerates at the boiling heat; mercurous salts form a yellow precipitate gradually turning green; tin-salts a white precipitate.—The *ammonium salt*, $(\text{CNS})^{12}\text{Cr}^6(\text{NH})^6 + 8\text{H}^2\text{O}$, is formed, with evolution of ammonia, when recently precipitated chromic hydrate is heated with ammonium sulphocyanate, but is more advantageously prepared like the potassium salt, namely by mixing a solution of 1 pt. ammonium dichromate, reduced by alcohol with addition of sulphuric acid and neutralised with ammonia, with 3 pts. of ammonium sulphocyanate, and heating the liquid to the boiling point.—The *sodium salt*, $(\text{CNS})^{12}\text{Cr}^6\text{Na}^6$, prepared by boiling a neutralised solution of chromic sulphate with sodium sulphocyanate, evaporating and treating the residue with alcohol, crystallises in thin, deliquescent laminae, having a lighter colour than the other double chromic sulphocyanates.—The *barium salt*, $(\text{CNS})^{12}\text{Cr}^6\text{Ba}^3$, prepared by mixing a neutral

solution of chromic chloride with barium sulphocyanate, crystallises in deliquescent, ruby-coloured, short, four-sided prisms.—The *silver salt*, $(\text{CNS})^{12}\text{Cr}^{\text{VI}}\text{Ag}$, is a brown-red, bulky precipitate, retaining, when dried over oil of vitriol, 53.9 p. c. water, which it gives off at 100° , the salt assuming a pale red colour. It is but imperfectly oxidised even by fuming nitric acid, is insoluble in ammonia, but dissolves with deep cherry-red colour in potassium cyanide. When suspended in water, it is decomposed

by caustic soda and by hydrogen sulphide.—The *lead salt*, $(\text{CNS})^{12}\text{Cr}^{\text{VI}}\text{Pb}_3 \cdot 4\text{PbH}^+\text{O}^2 + 8\text{H}^+\text{O}$, obtained by precipitation with lead acetate, has a rose-red colour, and when washed with water gives up lead sulphocyanate and is converted into $(\text{CNS})^{10}\text{Cr}^{\text{VI}}\text{Pb}_2 \cdot 4\text{PbH}^+\text{O}^2 + 5\text{H}^+\text{O}$. By boiling with water it is completely resolved into lead sulphocyanate, which dissolves, and a mixture of chromic oxide and lead oxide.—*Hydrochromic Sulphocyanate* or *Chromi-sulphocyanic acid*, $(\text{CNS})^{12}\text{Cr}^{\text{VI}}\text{H}^+$, is obtained, by decomposing the lead salt with hydrogen sulphide, as a deep wine-red, strongly acid liquid, which, when evaporated, gives off sulphocyanic acid, and leaves green, deliquescent *chromic sulphocyanate*, $(\text{CNS})^6\text{Cr}^{\text{VI}}$ (v. 506).

Lithium Sulphocyanate, obtained by saturating the acid with lithium carbonate, crystallises over oil of vitriol in very deliquescent laminæ. The *glucinum salt* crystallises less easily, and, like the preceding salt, is soluble in alcohol (Hermes, *J. pr. Chem.* xcvii. 465; *Jahresb.* 1866, p. 294).

Mercury Sulphocyanates (J. Philipp, *Pogg. Ann.* cxxxi. 86; *Jahresb.* 1867, p. 376;—Hermes, *loc. cit.*).—The white precipitate of *mercuric sulphocyanate*, $(\text{CNS})^2\text{Hg}$, formed by adding potassium sulphocyanate to mercuric nitrate, is soluble in excess of either salt. From boiling water or from a hot solution of mercuric oxide in sulphocyanic acid, it crystallises in nacreous laminæ (Philipp). It dissolves in cold hydrochloric acid and aqueous metallic chlorides, less easily in hot water, alcohol, and ether; decomposes at 165° , and explodes violently when triturated with potassium chlorate. Boiled with hydrochloric acid, it forms a yellow amorphous body, which is decomposed by boiling water into mercuric sulphide and hydrochloric acid. A solution of mercuric sulphocyanate in sulphocyanic acid deposits on evaporation yellow needle-shaped crystals of *hydromercuric sulphocyanate*, $(\text{CNS})^2\text{Hg} \cdot 2\text{CNSH}$ (Hermes). *Potassio-mercuric sulphocyanate*, $(\text{CNS})^2\text{HgK}$, is obtained by adding mercuric nitrate to potassium sulphocyanate till the white precipitate formed at first is converted into a yellow, crystalline mass, and then warming; or by directly dissolving mercuric sulphocyanate in potassium sulphocyanate. It is moderately soluble in warm water, but is decomposed by a large quantity of cold water, with separation of mercuric sulphocyanate. The compound $(\text{CNS})^2\text{Hg} \cdot \text{CNSK} + 2\text{H}^+\text{O}$, originally obtained by Böckmann (*Ann. Ch. Pharm.* xxii. 153), separates on mixing the concentrated solutions of its component salts, as a crystalline pulp; from dilute solutions in nacreous laminæ or slender prisms; the solution is not precipitated by potash or ammonia. The compound $\text{HgI}_2 \cdot 2\text{CNSK} + 2\text{H}^+\text{O}$ crystallises from a saturated solution of mercuric iodide in potassium sulphocyanate, as a yellowish, deliquescent salt, which, as well as the saturated solution, is decomposed by water, with separation of yellow mercuric oxide, which gradually changes to the red modification. Mercuric iodide dissolves, however, in a very dilute solution of potassium sulphocyanate. A solution containing mercuric chloride or bromide, together with excess of potassium sulphocyanate, first deposits chloride or bromide of potassium, and afterwards the double sulphocyanate of potassium and mercury. Concentrated solutions of mercuric chloride and potassium sulphocyanate gradually deposit mercuric sulphocyanate; but, on the other hand, mercuric chloride is formed when mercuric sulphocyanate acts upon potassium chloride (Philipp). The yellow precipitate formed by ammonia in a solution of potassio-mercuric sulphocyanate, and regarded by Claus as a mercuric oxy-sulphocyanate (v. 508), consists, according to Philipp, of *mercurammonium oxy-sulphocyanate*, $\text{NH}^+\text{Hg}^+ \cdot \text{CNS} \cdot \text{HgO}$. This body detonates when heated, turns grey when exposed to light, and is coloured brown by potassium iodide.

Mercurous Sulphocyanate, $(\text{CNS})^2\text{Hg}^2$, the existence of which is doubted by Hermes, is formed on adding potassium sulphocyanate to a large excess of dilute and somewhat acid mercurous nitrate. Small quantities of mercuric sulphocyanate and metallic mercury appear to be formed at first, but if the liquid is sufficiently acid, the grey or black precipitate becomes white after standing for some time, in consequence of the mercuric sulphocyanate uniting with the mercury to form the mercurous salt. Mercurous sulphocyanate is white, insoluble in water, blackened by alkalis; dissolves in hot hydrochloric acid, and in potassium sulphocyanate with separation of mercury, and behaves, when heated, like mercuric sulphocyanate, but does not swell up so much (Philipp).

Palladium Sulphocyanates.—Double salts of palladic and palladious sulphocyanate may be prepared by the method indicated by Buckton (v. 509) for the corresponding platinum-compounds. *Potassio-palladic sulphocyanate* forms large ruby-red anhydrous crystals, easily soluble in water and alcohol, melting and decomposing when heated, and oxidised by nitric acid, with separation of a white compound free from sulphur. *Potassio-palladious sulphocyanate* crystallises in dark red needles, *Palladammonium sulphocyanate*, (CNS)². N²H²Pd, is obtained in reddish-brown needles by the action of potassium sulphocyanate on palladammonium chloride (Croft, *Chem. News*, xvi. 53).

Silver Salts.—*Argentio sulphocyanate*, CNSAg, separates in crystals from solution in dilute ammonia; but a solution of this salt in concentrated aqueous ammonia deposits, on cooling, colourless, highly lustrous crystals of *argentammonium sulphocyanate*, CNS.NH²Ag, very much like argentammonium cyanide; they also, like the latter, very quickly give off ammonia when exposed to the air, but may be heated to 200° in aqueous ammonia without decomposition (Weith, *Zeitschr. f. Chem.* [2] v. 381; Gintl, *ibid.* vi. 183).

Thallious Sulphocyanate, CNSTl, crystallises, according to Hermes, in thin laminae, slightly soluble in cold, more soluble in hot water, insoluble in alcohol and other (Hermes). *Potassio-thallious sulphocyanate* crystallises from solution of the thallious salt in excess of potassium sulphocyanate in large shining prisms (Cars-tanjen, *Jahresh.* 1867, p. 281).

Sulphocyanates of Organic Bases.—When metallic sulphocyanates are added to solutions of salts of alkaloids (quinine, morphine, strychnine, nicotine, &c.) mixed with metallic salts, precipitates are formed, mostly gelatinous, and having little tendency to crystallise; they appear to consist of double sulphocyanates of an alkaloid and a metal (Skey, *Chem. News*, xviii. 150, 184).

Persulphocyanic acid, C²H²N²S² = (CyH)²S² (iv. 378), is most easily prepared, according to Hermes, by decomposing a solution of ammonium sulphocyanate in an equal weight of water with 3 vol. sulphuric acid of sp. gr. 1.34, the yellow crystals which separate being purified by recrystallisation from boiling water, which dissolves $\frac{1}{25}$ of them. The solution is coloured red by ferric chloride, like sulphocyanic acid, but lighter. With silver nitrate it forms a yellow precipitate, which easily decomposes, with formation of silver sulphide.

When ammonium sulphocyanate is treated with excess of sulphuric acid (sp. gr. 1.48), an oily liquid separates which gradually solidifies; this body, which in the liquid state has a very pungent odour and blisters the skin, is different from persulphocyanic acid and perhaps analogous to cyamelide. The same substance is formed in the preparation of hydrogen sulphocyanate by the decomposition of mercuric sulphocyanate with dry hydrogen sulphide. A colourless liquid then collects in the cooled receiver, a few drops of which placed upon a watch-glass quickly evaporate, leaving a yellow substance which gradually hardens (Hermes, *J. pr. Chem.* xcvi. 465).

SULPHOCYANIC ETHERS (Hofmann, *Berl. Akad. Ber.* 1868, pp. 24, 465; *Deut. chem. Ges. Ber.* 1868, pp. 25, 169, 201; *Zeitschr. f. Chem.* [2] iv. 201, 686; v. 671; *Proc. Roy. Soc.* xv. 254; xvii. 67; *Bull. Soc. Chim.* [2] ix. 478; *Jahresh.* 1868, p. 653).—These compounds form two isomeric groups, analogous to those of the alcoholic cyanides and cyanates (pp. 519, 522), which may be distinguished as sulphocyanic ethers, and isosulphocyanic ethers or sulphocarbimides. They are represented by the following formulæ, taking the methyl-compounds as examples:

the connection between the carbon-atoms within and without the alcohol-radicle being effected in the one case by the sulphur, in the other by the nitrogen.

The normal sulphocyanic ethers analogous to the nitriles were discovered by Cahours, and are produced by distilling a metallic sulphocyanate with an alcoholic chloride, or the potassium or calcium salt of methyl-sulphuric, ethyl-sulphuric acid, &c. (v. 519). The isosulphocyanic ethers or sulphocarbimides are produced, together with the corresponding monamines, by distilling the di-alcoholic sulphocarbamides with phosphoric anhydride: e.g.,

The phenyl-compound was obtained some years ago by Hofmann, and the naphthyl-compound by Hall (v. 521); and Hofmann has recently, by the reaction above mentioned, obtained other sulphocarbimides belonging to the fatty as well as to the aromatic group. The sulphocarbimides are distinguished from the normal sulphocyanic ethers by their intensely pungent odour, and by their capability of uniting directly with ammonia and with monamines, giving rise to alcoholic derivatives of sulphocarbamide. In these respects they resemble volatile oil of mustard, which is in fact allylic sulphocarbimide, $N(CS)(C^2H^5)$, and may be regarded as the type of the group. Hofmann, indeed, designates these bodies by the generic name of *Mustard-oils* (*Senföle*). It is remarkable, however, that allylic sulphocarbimide, and not normal allylic sulphocyanate (which is not known), is produced by distilling potassium sulphocyanate with allyl iodide.

Ethyl-sulphocarbimide or **Ethyle Isosulphocyanate**, $N(CS)(C^2H^5)$, is produced by distilling diethyl-sulphocarbamide with phosphoric anhydride or anhydrous hydrochloric acid, but is more easily prepared by the following process, depending on the decomposition of metallic ethyl-sulphocarbamates; thus:

When a solution of ethyl-sulphocarbamate of ethylamine (produced by direct combination of ethylamine with carbon bisulphide, p. 1049), is mixed with silver nitrate, a white precipitate of silver ethyl-sulphocarbamate is produced, which blackens even at ordinary temperatures, and more quickly when heated, with formation of silver sulphydrate and ethyl-sulphocarbimide, which latter passes over abundantly with the vapour of water on boiling, hydrogen sulphide being at the same time evolved, in consequence of the decomposition of the silver sulphydrate. An excess of silver nitrate must be avoided, as this salt, when boiled for some time with ethyl-sulphocarbimide, converts it into ethyl-cyanate (by substitution of O for S), which is ultimately resolved into carbon dioxide and ethylamine. Most other metallic salts react with ethyl-sulphocarbamic acid in the same manner as silver nitrate. Mercuric chloride is found to be convenient, as it does not attack the ethyl-sulphocarbimide nearly so fast as the silver nitrate; nevertheless a large excess of it should be avoided. In the process just described it is by no means necessary to start with pure ethylamine; the crude mixture of tertiary, primary, and secondary bases and ammonia, obtained by treating alcoholic ammonia with ethyl iodide and distilling with an alkali, answers the purpose quite as well. Diethylamine, in fact, is converted into ethyl-sulphocarbimide quite as easily as ethylamine; it unites with carbon bisulphide, especially in alcoholic solutions, forming diethyl-sulphocarbamate of diethyl-ammonium, which when decomposed with a metallic salt yields a salt of diethyl-sulphocarbamic acid, together with a diethylamine salt, and the former resolves itself into ethyl-sulphocarbimide and a mercaptide:

Methyl- and amyl-sulphocarbimide may be prepared in a similar manner.

Ethyl-sulphocarbimide, when purified by rectification, is a colourless liquid having a pungent and tear-exciting odour, and producing a burning pain when placed on the skin. It boils at 134° , has a vapour-density of 3.03 (cal. 3.02), and in the liquid state nearly the same specific gravity as water (Hofmann). According to Buff (*Zeitschr. f. Chem.* [2] iv. 730) it boils at 133.2° , and has a sp. gr. of 1.01913–1.019375 at 0° ; 0.997525 at 21.4° ; 0.997235 at 22° ; 0.87909–0.873513 at 133.2° . Ethyl-sulphocyanate, according to the same authority, boils at 146° , and has a specific gravity of 1.03300 at 0° ; 1.01261 at 19° ; 1.00238 at 23° ; 0.870135–0.869367 at 146° .

Ethyl-sulphocarbimide unites directly with *ammonia*, *ethylamine*, *methylamine*, and *aniline*, forming ethyl-, diethyl-, methyl-ethyl-, and ethyl-phenyl-sulphocarbamide (p. 1050).

Ethyl-sulphocarbimide digested for some hours at 110° with *ethyl alcohol*, unites with it, forming ethylic ethyl-oxy-sulphocarbamate, ethyl-xanthamide, or semi-sulphuretted ethyl-urethane, $CS \left\{ \begin{array}{l} NH(C^2H^5) \\ OC^2H^5 \end{array} \right.$; and, in like manner, when digested with *mercaptan* at 120° , it forms ethylic ethylsulphocarbamate, diethyl-xanthamide, or sulphuretted ethyl-urethane, $CS \left\{ \begin{array}{l} NH(C^2H^5) \\ SC^2H^5 \end{array} \right.$ (Hofmann, p. 1050).

Methyl-sulphocarbimide, $N\left\{\begin{smallmatrix}CS \\ CH_3\end{smallmatrix}\right.$, boils at 119° , melts at 34° , and solidifies at 26° . After distillation with aqueous vapour, it solidifies to a beautifully crystallised mass. Vapour-density obs. = 2.42; calc. 2.53.

Amyl-sulphocarbimide is best prepared by decomposition of the mercury salt of amyl-sulphocarbamic acid; but, instead of at once distilling off the product, it is better to cause the evolved vapours to condense and run back into the liquid for a considerable time. When the reaction is complete the mercuric sulphide is filtered off, and the amyl-sulphocarbimide is precipitated with water, dried with calcium chloride, and distilled. It is a liquid boiling at 183° – 184° , and having an odour like that of the ethyl compound, but less powerful. Vapour-density, obs. 4.40 (cal. 4.48) (Hofmann). According to Buff it boils at 182° , and has a sp. gr. of 0.957538 at 0° , 0.94189 at 17° , and 0.78749 at 182° .

Butyl-sulphocarbimide, $N\left\{\begin{smallmatrix}CS \\ C_4H_9\end{smallmatrix}\right.$, constitutes the essential oil of common scurvy-grass or spoon-wort (*Cochlearia officinalis*), which is often confounded with oil of mustard. It boils at 159° – 160° , and combines with ammonia, forming the splendidly crystallised compound *butyl-sulphocarbamide* or *butylic thiosinamine*, $N^2(CS)(C_4H_9)H^2$, which melts at 135° .

Isobutylamine (prepared from butyl alcohol of fermentation) treated with carbon bisulphide and mercuric chloride yields a butyl-sulphocarbimide of the same composition and nearly the same boiling point as the preceding, but differing in odour and forming with ammonia a thiosinamine which melts at 90° ; doubtless therefore *isobutyl-sulphocarbimide*, $N\left\{\begin{smallmatrix}CS \\ CH_2(CH)(CH_3)_2\end{smallmatrix}\right.$.

Watercress yields a similar oil, apparently containing a radicle of very high order (Hofmann, *Zeitschr. f. Chem.* [2] v. 400).

Phenyl-sulphocarbimide, $N\left\{\begin{smallmatrix}CS \\ C_6H_5\end{smallmatrix}\right.$.—The aromatic sulphocarbimides are not formed by decomposition of the metallic salts of phenyl-carbamic acid and its homologues. Phenyl-sulphocarbimide was originally obtained by the action of phosphoric anhydride on monophenyl-sulphocarbamide: $N^2(CS)(C_6H_5)H^2 = NH^2 + N(CS)(C_6H_5)$ (Hofmann, i. 756). It is also formed, together with triphenyl-guanidine, by the action of alcoholic iodine on a boiling alcoholic solution of diphenyl-sulphocarbamide (Hofmann), and by heating the same compound to 160° – 170° with strong hydrochloric acid (Merz & Weith). (See GUANIDINE, p. 655.) Heated with alcohol to a little above 100° , it forms *semi-sulphuretted phenyl-urethane*, $CS\left\{\begin{smallmatrix}NH(C_6H_5) \\ OC_6H_5\end{smallmatrix}\right.$, and with mercaptan it forms *sulphuretted phenyl-urethane*, $CS\left\{\begin{smallmatrix}NH(C_6H_5) \\ SC_6H_5\end{smallmatrix}\right.$ (Hofmann, p. 1050).

Tolyl-sulphocarbimide, $C_6H_5NS = \left\{\begin{smallmatrix}CS \\ C_6H_4(CH_3)\end{smallmatrix}\right.$, is prepared by heated ditolyl-sulphocarbamide with phosphoric anhydride. Aromatic vapours are then evolved, which condense to a yellow, quickly crystallising oil. An admixture of ditolyl-sulphocarbamide may be removed by crystallisation from ether, in which tolyl-sulphocarbimide is extremely soluble. This compound crystallises in white needles a centimetre long, having an odour very much like that of anise oil. It dissolves easily in alcohol, sparingly in water, boils at 237° , melts at 26° , and resolidifies at 22° . Heated with *toluidine*, it forms ditolyl-sulphocarbamide; with *ammonia* it forms monotolyl-sulphocarbamide; with *aniline*, phenyl-tolylsulphocarbamide, which is easily obtained in fine crystals.

Benzyl-sulphocarbimide, $C_6H_5NS = N\left\{\begin{smallmatrix}CS \\ CH_2(C_6H_5)\end{smallmatrix}\right.$, isomeric with the preceding, is produced, like the sulphocarbimides of the fatty series, by the action of mercuric chloride on benzyl-sulphocarbamate of benzylamine, inasmuch as benzylamine, $C_6H_5.CH_2(NH_2)$, is constituted like the amines of the fatty series, having the ammonia-residue NH^2 in the methyl group. On adding water to the distillate, the benzyl-sulphocarbimide separates in clear, heavy drops. It boils at 243° , and possesses in a high degree the odour of watercresses.

Menaphthylamine, treated with carbon bisulphide and mercuric chloride, likewise yields a sulphocarbimide.

All these compounds react like ethylic and allylic sulphocarbamides, especially with ammonia and amines (Hofmann).

Allyl-sulphocarbimide, or *Volatile oil of Mustard*, $N\left\{\begin{smallmatrix} CS \\ C^2H^3 \end{smallmatrix}\right.$.—It is remarkable that this compound, which exhibits all the essential characters of the sulphocarbimides above described, has not hitherto been produced artificially by analogous processes, but is obtained by a reaction which might rather be expected to yield allyl sulphocyanate, $S\left\{\begin{smallmatrix} CN \\ C^2H^3 \end{smallmatrix}\right.$, viz. by distilling potassium sulphocyanate with allyl iodide (v. 516), or with allyl bromide, or with the potassium salt of allyl-sulphuric acid. The product obtained by either of these processes is identical in every respect with natural oil of mustard (Tollens, *Zeitschr. f. Chem.* [2] v. 90).

Mustard-oil heated with alcohol a little above 100° unites with it, forming semi-sulphuretted allyl-urethane, $CS\left\{\begin{smallmatrix} NH(C^2H^3) \\ OC^2H^3 \end{smallmatrix}\right.$ (Hofmann, p. 1050). According to L. Henry (*Jahresb.* 1867, p. 379), it unites directly with dry *hydrobromic acid*, forming a crystalline compound, from which it is separated by water. With dry *hydrochloric acid* it forms a pitchy mass. Heated in alcoholic solution with *zinc* and *hydrochloric acid*, it is converted into allylamine, hydrogen sulphide, and carbon dioxide:

(Oeser, *Ann. Ch. Pharm.* cxxxiv. 7).

The following normal sulphocyanic ethers have been prepared by L. Henry (*Deut. chem. Ges. Ber.* ii. 207; *Zeitschr. f. Chem.* [2] v. 206).

Benzyl Sulphocyanate, $C^6H^5.CNS$ or $S\left\{\begin{smallmatrix} CN \\ C^6H^5 \end{smallmatrix}\right.$, is produced by heating benzyl chloride with potassium cyanate in a water-bath, and crystallises from alcohol in large transparent prisms, insoluble in water, slightly soluble in cold alcohol, easily in hot alcohol, also in ether and in carbon bisulphide. It has a sharp smell and taste, melts at $36^\circ-38^\circ$, and boils with partial decomposition at 256° . It unites readily with dry gaseous hydrogen bromide, forming a crystallised compound, insoluble in ether, immediately decomposed by water. Fuming nitric acid converts it into *nitrobenzyl sulphocyanate*, $C^6H^5(NO^2).CNS$, which is also produced from *nitrobenzyl chloride*, $C^6H^5(NO^2)Cl$, and potassium sulphocyanate, and crystallises from alcoholic solution in small brittle needles, volatilising at about 70° , and decomposing before it distils.

Glyceryl Sulphocyanate, $C^3H^5(CNS)^3$, is prepared by the action of potassium sulphocyanate in alcoholic solution at 100° on isotribromhydrin (produced by the action of bromine on allyl iodide); ordinary trichlorhydrin does not yield it. The compound separates from the alcoholic liquid in the crystalline form, and when recrystallised from alcohol forms small, white, shining, hard, brittle needles, having neither taste nor smell. It melts at 126° , and soon afterwards decomposes, giving off hydrogen cyanide and leaving a carbonaceous residue. It is quite insoluble in water, very slightly soluble in cold alcohol, much more soluble in boiling alcohol (Henry).

General Reactions of the Sulphocarbimides and Sulphocyanic Ethers.—The bodies of both these groups (taking the methyl-compounds for example) are ultimately produced from methyl-alcohol, carbon bisulphide, and ammonia, with elimination of 1 mol. water and 1 mol. hydrogen sulphide:

the nature of the resulting compound depending only on the order in which the reactions take place. In the case of methyl-sulphocarbimide we have:

and in that of methyl-sulphocyanate (see v. 504):

These considerations are supported by the following reactions: When an alcoholic solution of ethyl-sulphocarbimide is mixed with *zinc* and *hydrochloric acid*, hydrogen sulphide is given off for several days in continually decreasing quantity, but no carbon dioxide, whilst the liquid becomes filled with white needles of formic sulphaldehyde,

CH_3S ; and on mixing the liquid filtered from these crystals with strong soda-ley till the precipitated zinc oxide redissolves, and then adding alcohol, an oily layer of ethylamine and methyl-ethylamine rises to the surface. The principal reaction is:

and at the same time there is a secondary reaction, represented by the equation

When the isomeric compound, ethyl-sulphocyanate, is treated with zinc and hydrochloric acid, hydrogen sulphide is likewise evolved without carbon dioxide, but it is largely mixed with hydrogen cyanide, ethyl sulphhydrate, ethyl sulphide, and marsh gas, and on distillation a certain quantity of ethyl bisulphide is likewise obtained. The residue heated with soda-ley yields ammonia and methylamine. In this case the principal decomposition is represented by the equation:

and the secondary reaction by

The hydrogen cyanide is partly converted into methylamine: $\text{CNH} + 2\text{H}^2 = \text{N}(\text{CH}_3)\text{H}^2$.

The action of nascent hydrogen on allyl-sulphocarbimide is analogous to that on ethyl-sulphocarbimide (contrary to the observations of Oeser, p. 1057), the principal products being formic sulphaldehyde and allylamine:

while hydrogen sulphide, allylamine (no methyl-allylamine), and marsh gas are obtained as secondary products:

In the action of nascent hydrogen on sulphocyanic acid (zinc, hydrochloric acid, and potassium sulphocyanate) the reaction goes on in both ways; thus:

and

The hydrogen cyanide, however, appears only as methylamine.

Ethyl-sulphocarbimide heated with water in a sealed tube to 200° for several hours, is resolved into ethylamine, carbon dioxide, and hydrogen sulphide:

and

The same reaction takes place when concentrated hydrochloric acid is used instead of water, but it is then complete after an hour's heating to 100° . Ethyl sulphocyanate is but slowly decomposed by water even at high temperatures, considerable quantities remaining unaffected even after heating to 200° for several days. With strong hydrochloric acid, the decomposition is easier, the products being ethyl sulphide, ammonia, carbon dioxide, and hydrogen sulphide:

Allyl-sulphocarbimide is decomposed by water at high temperatures, especially in presence of hydrochloric acid, according to the equation:

At the same time, however, another reaction takes place, whereby a second liquid base is formed, boiling at a very high temperature and forming an amorphous platinum salt.

On ethyl-sulphocarbimide, dilute sulphuric acid acts in the same manner as water and hydrochloric acid. With strong sulphuric acid, on the contrary, it mixes, producing great rise of temperature, and after a few minutes extremely rapid evolution of carbon oxysulphide; the residue contains ethylamine sulphate:

In contact with water, and especially in presence of an alkali, the carbon oxysulphide is resolved into carbon dioxide and hydrogen sulphide.

Ethyl sulphocyanate is also but slowly acted upon by dilute sulphuric acid, rapidly by the concentrated acid, with considerable rise of temperature, and evolution of carbon dioxide and sulphur dioxide. On adding water and distilling, sulphuretted ethereal products pass over, and the brown residue heated with potash gives off considerable quantities of ammonia. The reaction appears therefore to be similar to that which takes place with water and hydrochloric acid, the sulphur being separated in connection with the ethyl group (Hofmann). Schmitt a. Glutz (*Zeitschr. f. Chem.* [2] iv. 723) by treating ethyl sulphocyanate with strong sulphuric acid, obtained carbonyl-disulphodiethyl, $\text{CO} \begin{Bmatrix} \text{SC}^2\text{H}^3 \\ \text{SC}^2\text{H}^3 \end{Bmatrix}$ isomeric with xanthic ether, $\text{CS} \begin{Bmatrix} \text{SC}^2\text{H}^3 \\ \text{OC}^2\text{H}^3 \end{Bmatrix}$, according to the equation:

Methyl sulphocyanate and amyl sulphocyanate yield homologous compounds.

On allyl-sulphocarbimide, sulphuric acid acts in the same manner as on the ethyl compound:

This reaction is well adapted for the preparation of allylamine.

Phenyl- and tolyl-sulphocarbimide, treated with sulphuric acid, yield carbon oxysulphide and the corresponding sulphuric acid: *e.g.*,

With nitric acid, ethyl-sulphocarbimide forms ethylamine, carbon dioxide, and sulphuric acid, whereas ethyl-sulphocyanate, as shown by Muspratt, yields ethyl-sulphurous acid, $\text{C}^2\text{H}^3\text{SO}^2\text{H}$. The homologous sulphocarbimides and allyl-sulphocarbimide act in the same manner.

Under the influence of sodium, ethyl sulphocyanate is completely resolved into cyanogen and ethyl bisulphide (Hofmann):

SULPHOMETHYLIC ALDEHYDE. CH^3S .—Syn. with FORMIC SULPH-ALDEHYDE (p. 622).

SULPHONAPHTHALENE CHLORIDE. $\text{C}^{10}\text{H}^7\text{SO}^2\text{Cl}$.—Syn. with NAPHTHYLSULPHUROUS CHLORIDE (p. 860).

SULPHONAPHTHALEIC ACID. $\text{C}^{10}\text{H}^6\text{SO}^4$.—Syn. with NAPHTHYLSULPHUROUS ACID (p. 860).

SULPHOPHENOLIC ACID. $\text{C}^6\text{H}^5\text{SO}^4$.—Syn. with PHENYLSULPHURIC ACID (p. 923).

SULPHOPHENYLENE-ETHYLENE. $\text{C}^6\text{H}^5\text{SO}^2 = \text{C}^6\text{H}^5\text{SO}^2.\text{C}^2\text{H}^3$ (Otto, *Ann. Ch. Pharm.* cxliii. 205).—This compound, originally observed by Kalle (*Jahresb.* 1861, p. 628) to be produced in the action of zinc-ethyl on phenylsulphurous chloride, and in the preparation of phenylsulphurous hydride by the action of sodium-amalgam on phenylsulphurous chloride (v. 564), may be prepared by treating the product of the action of sodium-amalgam on an ethereal solution of the chloride, after removal of the ether, with water and hydrochloric acid, washing the oil thereby separated with sodium carbonate, and dissolving it in ether, which leaves it behind on evaporation. It is an oily liquid, having a faint yellowish colour, and a peculiar unpleasant sweetish

odour, heavier than water, and insoluble therein, miscible in all proportions with alcohol, ether, and benzol. In hot water it dissolves slightly, forming a liquid which becomes milky on cooling. When heated alone, it is resolved into carbon, sulphurous oxide, and an oil having an odour of radishes. It dissolves with violet-red colour in warm fuming sulphuric acid; does not unite with alkaline bisulphites. By zinc and sulphuric acid, it is resolved into phenyl-sulphydrate and alcohol:

With fuming nitric acid it yields nitrophenylsulphurous acid, together with traces of nitrobenzene and picric acid.

SULPHOTOLUOLAMIDE, $\text{C}^6\text{H}^5.\text{SO}^2\text{NH}^2$, separates from a solution of sulphotoluolic bromide, $\text{C}^6\text{H}^5\text{SO}^2\text{Br}$, in concentrated aqueous ammonia, on evaporation, in large nacreous laminae. It is moderately soluble in hot alcohol and water, and melts at 139° – 140° (Otto & von Grüber, *Ann. Ch. Pharm.* cxlii. 92; *Jahresb.* 1866, p. 602).

SULPHOTOLUOLIC ACID. Syn. with TOLUENE-SULPHURIC or TOLYLSULPHUROUS ACID (p. 286).

SULPHOTOLYLENE-ETHYLENE. $\text{C}^6\text{H}^{10}\text{SO}^2 = \text{C}^6\text{H}^5\text{SO}^2.\text{C}^2\text{H}^4$ (Otto, *Ann. Ch. Pharm.* cxliii. 205).—This compound, obtained as a secondary product in the preparation of toluene-sulphurous acid, forms, after repeated crystallisation from absolute alcohol, small, shining, oblique, rhombic prisms, insoluble in water, slightly soluble in cold, easily in hot alcohol, ether, and benzol. It melts at 75° – 76° , and behaves in other respects like the corresponding phenylene compound. With zinc and dilute sulphuric acid it yields alcohol and nitrobenzylsulphydrate, $\text{C}^6\text{H}^5\text{S}$, identical with that which is obtained from sulphotoluolic chloride or from toluene-sulphurous acid. With fuming nitric acid, it yields nitrotoluene-sulphuric acid, $\text{C}^6\text{H}^5(\text{NO}^2)\text{SO}^2$, together with secondary products. With bromine in ethereal solution it forms the compound $\text{C}^{12}\text{H}^{20}\text{Br}^2\text{S}^2\text{O}^4$, which crystallises from ethereal solution in long needles, melting at 95° , and converted by heating with absolute alcohol into ethylic toluene-sulphate, $\text{C}^6\text{H}^5\text{SO}^2.\text{C}^2\text{H}^5$. This ether is likewise formed by the action of bromine on an alcoholic solution of sulphotolylene-ethylene.

When sulphotolylene-ethylene, dissolved in pure amylic ether or in a mixture of amylic ether and toluene, is treated with sodium-amalgam, there is formed, not sulphotolylene-amyline, but—together with metabenzyl bisulphide and a mercury-compound which crystallises in needles—either a body, $\text{C}^{12}\text{H}^{16}\text{S}^2\text{O}^4$, melting at 35° to 36° , or a compound, $\text{C}^{12}\text{H}^{16}\text{S}^2\text{O}^3$, crystallising in four-sided prisms and melting at 78° – 79° .

SULPHOXYBENZOIC ACID. See OXYBENZOIC ACID (p. 890).

SULPHUR. *Modifications*.—A soft, amorphous, yellow, opaque sulphur of sp. gr. 1.82–1.87, sparingly soluble in carbon bisulphide, is obtained, according to W. Müller (*Pogg. Ann.* cxvii. 404; cxxxiii. 347), by passing dry hydrogen sulphide over heated oxalic acid, or by passing sulphur-vapour evolved in a stream of carbon dioxide or hydrochloric acid into water. It does not lose its softness by pressure, and is but slightly soluble in carbon bisulphide. According to Sestini (*Bull. Soc. Chim.* [2] vii. 195), the supposed modification described by Müller is nothing but sulphur in the utricular form, which it assumes on rapid condensation in contact with the air. According to Berthelot, on the other hand (*ibid.* 187), sulphur condensed in water is identical with that which is condensed in the air, only while in the soft elastic state; when hardened it contains a different amount of insoluble sulphur. According to De Luca and Ubaldini (*Compt. rend.* lxiv. 1200), sulphur separated from aqueous sulphurous acid (with simultaneous formation of pentathionic acid) by the action of hydrogen sulphide, consists partly of the insoluble modification, the proportion varying with the duration of the contact and other conditions of the experiment. When the sulphurous acid is in excess the insoluble modification predominates.

Sulphur may be crystallised from fusion in the rhombic form (v. 530), by filling a long-necked flask, having a capacity of 150–200 centimetres, with pure sulphur, drawing out the neck to a capillary orifice with two or three bends, melting the sulphur in an oil-bath at 120° , and then immersing the flask in water at 90° . The sulphur then remains liquid for a long time, and crystals gradually form, both on the surface and within the mass, and may be at least partially isolated by inverting the flask, so that the still fluid portion may run into the neck. These crystals are transparent, agree in form and in their angles with native sulphur, and may be kept without alteration. Their formation is facilitated by adding a few drops of carbon bisulphide to the sulphur before fusion.

The solubility of sulphur in carbon bisulphide and other liquids has been determined by Cossa:

Temperature	Sulphur in 100 pts. CS ²	Temperature	Sulphur in 100 pts. CS ²
—11°	16.54	22°	46.06
—6°	18.75	38°	94.67
0°	23.99	48.5°	146.21
+15°	37.15	55°	181.34
18.5°	41.65		

The dissolution is attended with absorption of heat: when 20 pts. sulphur are dissolved in 50 pts. of the bisulphide at 22°, the fall of temperature amounts to about 5°. The saturated solution boils at 55° (pure carbon bisulphide at 46.8°).

100 pts. benzene dissolve	{ 0.965 pts. sulphur at 26°.
	{ 4.377 " " 71°.
100 pts. toluene "	1.479 " 23°.
100 pts. ethyl oxide "	0.972 " 23.5°.
100 pts. chloroform "	1.205 " 22°.
100 pts. phenol "	16.35 " 174°.
100 pts. aniline "	85.96 " 130°.

Coal-naphtha dissolves about 2 p. c. sulphur at ordinary temperatures, nearly half its weight at temperatures near the boiling point. The solvent power of coal-naphtha for sulphur increases with its specific gravity; certain heavy coal-tar oils dissolve as much as 115 p. c. sulphur at 110°, and an almost unlimited quantity at 120° (E. Pelouze, *Compt. rend.* lxxviii. 1179; lxi. 56).

Reactions.—When a series of electric sparks is passed through a mixture of sulphur-vapour and oxygen, combination takes place, sometimes with slight explosion, and sulphurous oxide is produced. Hydrogen and sulphur unite easily under similar circumstances, forming H₂S. With nitrogen no reaction takes place. With monoxide and dioxide of nitrogen, sulphurous oxide and nitrogen are formed, and on passing the products into a dry glass vessel cooled with water, splendid leaden-chamber crystals are obtained. Carbon monoxide unites easily with sulphur, under the same circumstances, forming carbon oxysulphide; carbon dioxide, which is resolved by the electric spark into the monoxide and oxygen, yields carbon oxysulphide and sulphurous oxide (Chevriér, *Compt. rend.* lxi. 136).

When hydrogen gas is passed through boiling sulphur, hydrogen sulphide is abundantly produced. Sulphur likewise acts on boiling aniline, giving rise to rapid evolution of hydrogen sulphide and formation of a sulphuretted base. Other organic bodies, as acetalinide, glycerin, naphthalene, &c., are likewise attacked by sulphur (Merz & Weith, *Zeitschr. f. Chem.* [2] v. 603).

Detection by the Spectroscope.—The flame of sulphur burning in the air gives a continuous spectrum; so likewise does that of hydrogen burning in oxygen. But when sulphur-vapour is passed into a hydrogen-flame, a very beautiful and complicated spectrum is formed, which was first observed by Mulder in 1864. This spectrum is not seen in the hot part of the flame, where the oxygen enters, but only in the inner part, consisting of nearly pure hydrogen heated to a comparatively low temperature; this part of the flame may also be distinguished with the naked eye, by its fine blue colour. On cooling the sulphuretted flame, the same colour appears at the cooled part. The spectrum of sulphur consists of a number of bright and nearly equidistant lines in the green and the blue. Towards the violet these lines unite in bands. When a flame of pure hydrogen burning from a platinum jet is directed over the surface of sulphuric acid, the cooled part of the flame acquires a splendid blue colour with a tinge of violet, and exhibits the spectrum above described, whence it may be inferred that the sulphur is separated in the free state in the reducing flame. On passing vapour of sulphuric or sulphurous acid into the flame, the axis becomes coloured in the same manner as in the experiment with sulphur-vapour. The same characteristic colour is observed when a hydrogen flame is directed upon a crystal of sodium sulphate, ammonium sulphate, alum, gypsum, &c., or of a sulphite or hyposulphite; with barium sulphate however it is not produced. The flame of hydrogen burning under a bell-jar frequently exhibits a blue colour at the edges, and the same blue tint is almost always observed when the flame of hydrogen is passed over the surface of a glass vessel. This blue flame exhibits the spectrum of sulphur, and the presence of that element in the flame is due to reduction of sulphates in the glass or to sulphuric acid in the air (Salet, *Compt. rend.* lxxviii. 404; *Zeitschr. f. Chem.* [2] v. 223). W. F. Barrett

also has observed that when a pure hydrogen-flame is directed on the surface of various solid bodies, metallic or non-metallic, and on several liquids, a ring of deep blue light is produced, due also to sulphur, derived from the air (*Phil. Mag.* [4] xxx. 321; *Jahresb.* 1865, p. 139). On the spectrum of sulphur see also SPECTRAL ANALYSIS (p. 1032); further, Salet (*Compt. rend.* lxxiii. 559), and Ditte (*ibid.* 622); also *Chem. Soc. J.* [2] ix. 1146, 1146.

On the estimation of sulphur in iron, see Eggertz (*Chem. News*, 1868, p. 207); in organic bodies, ANALYSIS, ORGANIC (p. 148).

Recovery of Sulphur from Alkali-waste (v. 529).—A historical notice of the several processes devised for this purpose has been given by A. Scheurer-Kestner (*Bull. Soc. industr. de Mulhouse*, février 1858; *Bull. Soc. Chim.* [2] ix. 419). The methods proposed down to the year 1855 had for their object to utilise these residues for the preparation of hyposulphites, or to evolve hydrogen sulphide from them, and from this to separate the sulphur or prepare sulphurous acid. The subsequent improvements relate: 1. To the oxidation of the residues by air in such a manner that the soluble oxidation-product may be decomposed by acids without evolution of gas, and that only one equivalent of acid may be required for the separation of several equivalents of sulphur.—2. The use of crude manganese solution (chlorine-residues) in place of hydrochloric acid.—3. The extraction of the pure fused sulphur.

The first problem has been solved by Guckelberger and by Schaffner. Guckelberger in 1858 began experiments, which were carried on from 1859 to 1861 under his direction by L. Mond, and had for their object to determine the duration of oxidation for thin layers which would yield the maximum quantity of hyposulphites. The quantity of sulphur present in the form of hyposulphites was found to be as follows:

	After 14 days.	After 4 weeks.	After 6 weeks.	After 10 weeks.
For 100 pts. of the moist residue	2.5	4.5	1.0	0.0
For 100 pts. of the dry residue	2.6	4.0	12.0	1.0

Guckelberger also found that the oxidation takes place more easily, and with evolution of heat, when the residues are exposed to the air in heaps of considerable size, and that then also the further rapid oxidation of the calcium sulphides may be avoided. In this manner (1862) he obtained solutions from which the sulphur was separated by acids without evolution of gas, but it was only in 1864 that he prepared the regenerated sulphur on the manufacturing scale. Patents for the oxidation of these residues were taken out by Mond in 1861 and 1863. His last process (1867) is as follows: The residues, without removal from the lixiviating tanks, are treated for 12 to 24 hours with a current of air driven by a ventilator till they assume a yellow-green colour, after which they are subjected to methodical lixiviation, and this treatment is repeated several times. The oxidation must be so regulated that the liquor may contain 2 mol. sulphide to 1 mol. hyposulphite (if it is carelessly conducted the hyposulphite is converted into sulphite and sulphydrate of calcium). The quantity of acid required to nearly saturate the lime (present as sulphide and hyposulphite) is then added, taking care to leave the liquid slightly alkaline, and the whole is heated to 60° by a current of steam. The nearly pure sulphur thus separated is washed and melted. The yield amounts to about $\frac{2}{3}$ of the total quantity of sulphur in the alkali-waste, the other $\frac{1}{3}$ being left behind as sulphite and sulphate of calcium. To determine the quantities of hyposulphite, &c., in the liquors:—1. The quantity of hyposulphite is titrated with iodine, after the sulphides and sulphydrates have been decomposed by excess of zinc-chloride.—2. A second sample is mixed with iodine and starch till a blue colour appears, and after decoloration with sodium hyposulphite it is neutralised with acetic soda. According to the equations $\text{CaS} + \text{I}_2 = \text{CaI}_2 + \text{S}$; $\text{CaHS} + \text{I}_2 = \text{CaI}_2 + \text{S} + 2\text{HI}$; $2\text{HI} + \text{Na}_2\text{O} = 2\text{NaI} + \text{H}_2\text{O}$, the second titration with iodine gives the total quantity of hyposulphite, sulphide, and sulphydrate; the titration with soda gives the amount of sulphydric acid (Mond, *Chem. News*, xv. 183; xvi. 27, 41; *Jahresb.* 1867, p. 901). See also Schaffner (*Zeitschr. f. Chem.* [2] v. 566; *Dingl. pol. J.* cxcii. 308; *Jahresb.* 1868, p. 925).

The use of crude manganese solution instead of hydrochloric acid was tried by Townshend and Walker in 1860, and afterwards successfully carried out by P. W. Hofmann (*Chem. News*, xvi. 163; *Jahresb.* 1866, p. 857); by E. Kopp (*Ann. Ch. Phys.* [4] vii. 5, 63; *Bull. Soc. Chim.* [2] 335, 440; *Chem. News*, xii. 264, 290; xiii. 27, 40, 111, 140; *Jahresb.* 1865, p. 779; further: *La dénaturation et utilisation des résidus de la fabrication de la soude et du chlorure de chaux*, Paris, 1868; abstr. *Jahresb.* 1868, p. 923); see also P. W. Hofmann (*Chem. News*, xvi. 163; *Jahresb.* 1866, p. 857), and Rosenstiehl (*Bull. Soc. Chim.* [2] ix. 339; *Jahresb.* 1868, p. 923).

OXYGEN-COMPOUNDS OF SULPHUR.

1. **Hyposulphurous Acid.** $\text{H}^2\text{SO}^2 = \begin{matrix} \text{H} \\ \text{H} \end{matrix} \text{SO}^2$.—*Hydrosulphurous Acid* (Schützenberger, *Zeitschr. f. Chem.* [2] v. 545).—This acid is produced by the action of zinc on aqueous sulphurous acid. The metal dissolves without evolution of hydrogen, forming a yellow solution which possesses a decolorising power much greater than that of sulphurous acid itself, throws down from cupric sulphate a precipitate of cuprous hydride, Cu^2H^2 , mixed, if the copper solution is in excess, with metallic copper, and immediately reduces the metals from silver and mercury salts. The solution thus obtained is, however, very unstable; its decolorising power attains a maximum in a few minutes, then diminishes, while at the same time it loses its yellow colour and becomes milky from separation of sulphur; it then contains thiosulphuric acid, $\text{H}^2\text{S}^2\text{O}^2$.

A more definite product is obtained by immersing clippings of zinc in a concentrated solution of acid sodium sulphite contained in a closed vessel. The zinc then dissolves as before without evolution of hydrogen, the reaction being completed in about half an hour, and an abundant crystallisation of zinc-sodium sulphite is produced. The decanted liquid, which possesses very great decolorising power, becomes very hot on exposure to the air, losing at the same time its characteristic properties, and afterwards containing nothing but the double salt just mentioned, together with acid sodium sulphite. To isolate a definite compound, the solution (about half a litre) is poured into a flask holding about two litres, and three-fourths filled with strong alcohol, and the flask is hermetically sealed. A crystalline precipitate is then immediately formed, consisting for the most part of zinc-sodium sulphite, while nearly all the bleaching compound remains dissolved in the alcohol. This solution decanted into a flask quite filled with it, well closed, and left to stand in a cool place, solidifies in a few hours to a mass of slender colourless needles, which must be pressed as quickly as possible between folds of linen, and dried in a vacuum, as it becomes very hot if exposed to the air in the moist state; when dry, however, it is not affected by oxygen. This salt contains but a small quantity of zinc, from which it may be freed by solution in water and reprecipitation with alcohol. It then consists of sodium hypsulphite, NaHSO^2 . It is very soluble in water, soluble also in dilute alcohol, insoluble in strong alcohol. Its solution possesses all the decolorising and reducing powers above mentioned. The crystals when exposed to the air are completely converted into acid sodium sulphite, NaHSO^3 , without formation of other products. When heated in a tube, they give off sulphur and sulphurous acid, together with a little water, and leave a residue of sodium sulphate and sulphide.

Hyposulphurous acid, which is much more unstable than its sodium salt, may be separated therefrom by treating the crystals with oxalic acid. A deep orange-yellow solution is then formed, possessing great decolorising power, and quickly becoming colourless, with deposition of sulphur. The formation of the acid by the action of zinc on sulphurous acid is represented by the equation:

The same reaction takes place with other metals, as iron or manganese. The formation of thiosulphates in all these cases is only a secondary reaction due to the slow and spontaneous decomposition of the hypsulphite.

When a porous earthenware cell filled with acid sodium sulphite is immersed in weak sulphuric acid, and the liquid subjected to electrolysis, the negative pole dipping into the acid sulphite, oxygen is evolved at the positive pole, while at the negative pole no gas is evolved, but the sulphite is converted into hypsulphite. By replacing the nitric acid in a Bunsen's cell with acid sodium sulphite, a combination is obtained, which is very little inferior in intensity to the ordinary Bunsen's battery, and remains constant for a considerable time (Schützenberger).

Ethyl-hyposulphurous Acid. $\text{C}^2\text{H}^3\text{SO}^2 = \begin{matrix} \text{C}^2\text{H}^3 \\ \text{H} \end{matrix} \text{SO}^2$ (Wischim, *Ann. Ch. Pharm.* cxxxix. 364).—This acid, called by its discoverer *ethyl-sulphurous acid*, is produced as a zinc-salt by the action of zinc-ethyl on sulphuric anhydride, $2\text{SO}^2 + \text{Zn}(\text{C}^2\text{H}^3)^2 = \text{SO}^2 + \text{ZnSO}^4 + \text{C}^2\text{H}^3$; and $2\text{SO}^2 + \text{Zn}(\text{C}^2\text{H}^3)^2 = \text{Zn}(\text{C}^2\text{H}^3\text{SO}^2)^2$. When zinc-ethyl is carefully mixed with an equivalent quantity of sulphuric anhydride in a strong tube sealed and filled with dry carbon dioxide, a violent reaction takes place, very apt to give rise to explosion, and zinc ethyl-hypsulphite is formed together with combustible gases, sulphurous anhydride, zinc sulphate, zinc sulphide and metallic zinc. Ethyl-hyposulphurous acid is also formed (contrary to the

statement of Hobson (iii. 1004), by the action of zinc-ethyl on sulphurous anhydride. When a cooled solution of zinc-ethyl in 50 vol. ether is saturated with sulphurous anhydride, the residue left after evaporation of the ether contains the zinc salt of ethyl-hyposulphurous acid, $\text{Zn}(\text{C}^2\text{H}^5\text{SO}^2)^2 + \text{H}^2\text{O}$, which dissolves in water, less easily in hot alcohol of 90 p. c., and crystallises from the latter in soft nacreous scales. The barium salt, $\text{Ba}(\text{C}^2\text{H}^5\text{SO}^2)^2$ (at 100°), obtained by decomposing the zinc salt with baryta-water, is very soluble in water, less soluble in alcohol, and separates on evaporating the solution in a vacuum, in crystalline crusts. The copper salt, $\text{Cu}(\text{C}^2\text{H}^5\text{SO}^2)^2$, obtained by decomposing the barium salt with cupric sulphate, and evaporating in a vacuum, forms pale green, deliquescent, crystalline crusts, which give off water and a little of vitriol, and assume a darker green colour. It is decomposed by evaporation over the water-bath. The silver salt, $\text{Ag}(\text{C}^2\text{H}^5\text{SO}^2)$, formed by neutralising the acid with silver carbonate, crystallises by evaporation in the dark, in highly lustrous laminae moderately soluble in water. The free acid, or hydrogen salt, $(\text{C}^2\text{H}^5)\text{HSO}^2$, obtained by decomposing the barium salt with sulphuric acid, remains after evaporation in a vacuum, as a syrup, having an agreeable sour taste, and soluble in all proportions in water. By nitric acid of sp. gr. 1.4, it is converted into ethyl sulphurous acid, $\text{C}^2\text{H}^5\text{SO}^2$, together with a crystallisable compound soluble in water.

2. Sulphurous Compounds.

Sulphurous Oxide or *Anhydride*, SO^2 , is formed by the action of sodium-amalgam or of zinc and hydrochloric acid upon a dilute solution of barium hypsulphate: $\text{S}^2\text{O}^3 + \text{H}^2 = 2\text{SO}^2 + \text{H}^2\text{O}$ (Otto, *Zeitschr. f. Chem.* [2] iv. 168). It may be conveniently prepared by heating 2.4 pts. of dehydrated and pulverised ferrous sulphate with 1 pt. of sulphur: $\text{FeSO}^4 + \text{S}^1 = \text{FeS} + 2\text{SO}^2$. The residual ferrous sulphide may be used for the preparation of hydrogen sulphide. The gas is still more easily evolved from a mixture of 1 pt. dehydrated cupric sulphate and 3 pts. sulphur; if the heat is not raised to redness, the residue consists of indigo-coloured cupric sulphide. In either case, wide gas-delivery tubes must be used, as narrow ones would be stopped up by the sulphur (Stolba, *Bull. Soc. Chim.* [2] vii. 240).

According to Stas (*Jahresb.* 1867, p. 150), sulphurous oxide exhibits different properties, accordingly as it is prepared and kept in the dark or exposed to light. The gas prepared in the dark by heating sulphuric acid with charcoal, wood, or metals, or by the burning of sulphur—as well as its aqueous solution—produces in neutral or slightly acid solutions of silver nitrate or sulphate (but not in strongly acidulated solutions) a pure white precipitate of silver sulphite without colouring the solution. The precipitate remains white in the dark, but when exposed to light in presence of excess of sulphurous acid, it is converted into a mixture of silver sulphate and metallic silver. Acid prepared as above converts chlorate, bromate, or iodate of silver into chloride, bromide, or iodide, without separation of silver or formation of silver sulphide. Sulphurous acid which has been exposed to light, and in a less degree also that which has been prepared by heating manganese dioxide or sulphuric acid with sulphur, produces in acid as well as in neutral solutions of silver nitrate or sulphate, a gray precipitate, the supernatant liquid at the same time turning black, and ultimately depositing silver sulphide. Chlorate, bromate, and iodate of silver are converted by this modification of the acid, even in perfect absence of light, into mixtures of chloride, bromide, or iodide, with sulphide of silver.

Liquefied sulphurous oxide dissolves many substances—as phosphorus, sulphur, iodine, bromine, chloroform, carbon bisulphide, benzol, ether, resins—without alteration, or mixes with them, and more easily when warmed with them in a sealed tube than in the cold. Concentrated sulphuric and phosphoric acids are not dissolved by sulphurous oxide; nitric acid forms with it a crystalline substance which has the appearance of the leaden-chamber crystals, and disappears on further addition of sulphurous oxide (Sestini, *Bull. Soc. Chim.* [2] x. 226).

According to W. Schmid (*Zeitschr. f. Chem.* [2] iv. 50), sulphurous oxide and hydrogen sulphide do not act on one another when perfectly dry; but on introducing a wet glass rod into the mixture, sulphur is instantly deposited upon it, and pentathionic acid is produced.

Sulphurous acid in presence of a large quantity of water reduces nitrous and nitric acid to nitrogen monoxide (Weber). See NITROGEN OXIDES, p. 871.

A strip of filter-paper moistened with a mixed solution of ferric sulphate and potassium ferricyanide, and introduced into the vapour of burning sulphur, immediately acquires a fine blue colour. The same reaction is produced with a solution of sulphurous acid, or with a sulphite or thiosulphate, but not with sulphates, excepting ferrous sulphate (E. Smith, *Chem. News*, xvi. 223).

Sulphurous acid in aqueous solution is reduced by *zinc* to hyposulphurous acid, SH^+O^2 , the sulphur-analogue of formic acid (Schützenberger, p. 1063).
Sulphurous acid acts upon *stannous chloride* according to the following equations:

Moreover, on adding a cupric solution to a mixture of sulphurous acid with a large excess of stannous chloride, a black-brown precipitate is formed. Sulphurous acid reacts in the same manner with stannous chloride in presence of nearly all metals that are precipitable by hydrogen sulphide. Thus on passing gaseous sulphurous oxide through the hydrochloric acid solution of stannous chloride and *antimonious chloride* at ordinary temperatures, a yellow precipitate is formed which gradually turns red. At about 70° the reaction is quicker, and a dark red precipitate is immediately formed, free from tin, and consisting of a mixture of antimonious oxide and sulphide:

In like manner, sulphurous acid throws down from mixtures of stannous chloride with *platinic chloride*, *arsenic acid*, *copper salts*, or *bismuth salts*, the sulphides of platinum, arsenic, copper, or bismuth, the whole of the tin remaining in solution as stannic chloride. From a mixture of stannous chloride and *cadmium sulphate* the whole of the tin is precipitated as stannic sulphide, and from a mixture of stannous chloride and *lead acetate*, sulphurous acid throws down sometimes a tin sulphide, sometimes a yellow precipitate, which blackens with potash and consists of sulphide and chloride of lead (Foderow, *Zeitschr. f. Chem.* [2] v. 15).

Sulphurous Chloride or *Thionyl Chloride*, SOCl^2 , which Schiff obtained by the action of phosphorus pentachloride on sulphurous oxide (v. 542), is also produced by the action of hypochlorous anhydride upon sulphur chloride, SCl^2 , cooled to 10° , which contains sulphur in suspension. Separated by distillation from the sulphur chloride (which boils at 139°), it is a colourless, pungent liquid, having a sp. gr. of 1.675 at 0° , and boiling at 78° (Wurtz, *Compt. rend.* lxii. 460).

METALLIC SULPHITES.—*Ammonio-cuprous sulphite*, $(\text{Cu}^2)^+(\text{NH}^4)^2(\text{SO}^3)^2 + 2\text{H}^2\text{O}$, is obtained in six-sided colourless plates by passing sulphurous oxide into an ammoniacal solution of cupric sulphate, or by digesting ammoniacal cupric acetate with metallic copper till it is decolorised, and then saturating with sulphurous acid. The *sodio-cuprous salt*, $(\text{Cu}^2)^+\text{Na}^2(\text{SO}^3)^2 + 2\text{H}^2\text{O}$, is produced by adding sodium sulphite to concentrated cupric acetate till a permanent precipitate is formed; the liquid when left at rest deposits the double salt in colourless microscopic crystals mixed with an orange-yellow compound. By prolonged contact with the mother-liquor these crystals change into microscopic quadratic tablets, apparently consisting of $\text{Cu}^2\text{Na}^2(\text{SO}^3)^2 + 11\text{H}^2\text{O}$ (Commaillo, *J. Pharm.* [4] vi. 107).

Gold Sulphites.—A double salt approximating in composition to the formula $(\text{NH}^4)^2\text{SO}^3 \cdot 3(\text{NH}^4\text{Au})\text{SO}^3 + 3\text{H}^2\text{O}$ is formed by gradually adding a nearly neutral solution of auric chloride to a gently warmed solution of 'ammon sulphite' (? sulphimic acid, NH^4SO^2) in strong ammonia. A precipitate of fulminating gold is formed at first, which afterwards dissolves, and the solution after some time deposits the double salt in six-sided laminae. The mother-liquor contains an ammonio-aurous sulphite. When acid sodium sulphite is added by small portions to a strongly alkaline and nearly boiling solution of sodium aurate, a yellow precipitate is formed, which disappears on further addition of ammonium sulphite, the solution then containing a *sodio-aurous sulphite* analogous to the *potassio-aurous salt* described by Frémy (v. 645). A drop of the solution left to evaporate under the microscope leaves the double salt in purple-red crystals, but it cannot be purified by recrystallisation. The solution yields with barium chloride, first a white precipitate of barium sulphite and sulphate, and afterwards a purple-red precipitate of *bario-aurous sulphite*, $\text{Au}^2\text{SO}^3 \cdot 3\text{BaSO}^3 + 2\text{H}^2\text{O}$. From this barium salt the corresponding potassium and sodium salts may be obtained by double decomposition with alkaline carbonates. The sodium salt contains $\text{Au}^2\text{SO}^3 \cdot 3\text{Na}^2\text{SO}^3 + 3\text{H}^2\text{O}$. The solution of this salt gives white precipitates with lead and silver salts, no precipitate with salts of calcium, strontium, magnesium, aluminium, zinc, copper, cobalt, or nickel (A. Haase, *Zeitschr. f. Chem.* [2] v. 536).

Platinum Sulphites.—*Double platinum sulphites* are obtained by passing sulphurous oxide into water in which platinic hydrate is suspended, till the hydrate begins to dissolve rapidly, mixing the filtered solution with an alkaline sulphite, and then with the corresponding carbonate in sufficient quantity to produce an alkaline reaction. The double salts then separate as red-brown crystalline precipitates. The *potassium salt*,

$K^2SO^3 \cdot (PtO)^2SO^3 + H^2O$ or $(PtO)^2\left\{ \begin{smallmatrix} 2(SO)^{''} \\ K^2 \end{smallmatrix} \right\} O^3 + H^2O$, is somewhat soluble in water, and

separates from the solution by slow *evaporation* in the pulverulent form; the greater part however is reduced and crystallises out as potassio-platinous sulphite. The *sodium salt*, $2Na^2SO^3 \cdot (PtO)^2SO^3 + 2H^2O$ or $3(SO)^{''} \cdot Na^4(PtO)^2 \cdot O^3 + 2H^2O$, is granulo-crystalline, and somewhat lighter in colour than the potassium salt. The easily soluble *ammonio-platinum salt* is decomposed by *evaporation*, leaving the platinous double salt. All these platinum double sulphites are decomposed by hydrochloric acid, with formation of platinous and platinic chloride. Their solutions are reduced by hydrogen sulphide, but the platinum is not precipitated by hydrogen sulphide or ammonium sulphide except on addition of hydrochloric acid. With barium chloride they form a yellow precipitate soluble in acids, and containing all the platinum (Birnbaum, *Ann. Ch. Pharm.* cxxxix. 164; *Jahresb.* 1866, p. 269).

Potassio-platinous sulphite, $3K^2SO^3 \cdot Pt^2SO^3 + 2H^2O = \left(\begin{smallmatrix} (S'O)^{''} \\ K^2Pt^2 \end{smallmatrix} \right) O^3 + 2H^2O$, is obtained by passing sulphurous oxide in excess through a solution of potassium sulphite in which platinic hydrate is suspended. The colourless solution yields the double salt on *evaporation* in stellate groups of needles moderately soluble in water. The solution added to sodium salts throws down the sodio-platinous sulphite described by Litton a. Schnedermann (v. 549), the amount of water in which was found by Birnbaum to correspond to the formula $3Na^2SO^3 \cdot PtSO^3 + 3H^2O$. The *ammonium salt*, $3(NH^4)^2SO^3 \cdot PtSO^3 + 3H^2O$, is prepared like the potassium salt, which it resembles in form and solubility; it is precipitated from its aqueous solution by alcohol, and afterwards dissolves but slowly in water. Its hydrochloric acid solution mixed with alcohol and ammonia yields a precipitate of the salt described by Liebig (*Gmelin's Handbook*, vi. 298), with an amount of water corresponding to the formula $(NH^4)^2SO^3 \cdot PtSO^3 + H^2O$. The aqueous solutions of all these salts give with barium chloride a white precipitate soluble in hydrochloric acid, and containing the whole of the platinum (Birnbaum, *loc. cit.*).

Platinosochlorosulphurous Acid. $Pt^2\left\{ \begin{smallmatrix} Cl \\ SO^3H \end{smallmatrix} \right\}$.—This compound is obtained, in combination with sal-ammoniac, by adding ammonium platinochloride to concentrated aqueous sulphurous acid, warming the mixture on the water-bath, and replacing the sulphurous acid as it evaporates. On evaporating the resulting solution to the crystallising point, again mixing it with a slight excess of sulphurous acid, and leaving it to evaporate over oil of vitriol and quick lime, a few crystals of ammonium platinosochloride, $2NH^4Cl \cdot PtCl^2$, first separate, and then long orange-yellow needles of the compound $Pt\left\{ \begin{smallmatrix} Cl \\ SO^3H \end{smallmatrix} \right\} \cdot 2NH^4Cl$. By neutralising the solution with potassium carbonate, the corresponding potassium salt, $Pt\left\{ \begin{smallmatrix} Cl \\ SO^3K \end{smallmatrix} \right\} \cdot 2NH^4Cl$, is obtained in well-defined rhombic crystals. The formation of the chloroplatinosulphurous acid is represented by the equation—

The compound $PtClSO^3H \cdot 2NH^4Cl$ is likewise formed, and even with greater facility, by directly dissolving ammonium platinosochloride in aqueous sulphurous acid. In like manner, by dissolving the same salt in a concentrated solution of neutral ammonium sulphite, a compound of ammonium platinosochlorosulphite with ammonium sulphite, $Pt\left\{ \begin{smallmatrix} Cl \\ SO^3NH^4 \end{smallmatrix} \right\} \cdot (NH^4)^2SO^3 + 3H^2O$, is obtained in light yellow crystals apparently belonging to the monoclinic system. When potassium platinochloride is treated with excess of sulphurous acid, the yellow solution first deposits crystals of potassium sulphate; and on mixing the remaining liquid, which does not of itself yield any crystallisable compound, with potassium chloride, well-defined rhombic crystals are obtained, consisting of the salt $Pt\left\{ \begin{smallmatrix} Cl \\ SO^3K \end{smallmatrix} \right\} \cdot 2KCl$. Lastly, by treating ammonium platinosochloride, $2NH^4Cl \cdot PtCl^2$, with acid ammonium sulphite, both atoms of chlorine in the platinous chloride may be replaced by the univalent residue SO^3H , and the compound $Pt\left\{ \begin{smallmatrix} SO^3H \\ SO^3H \end{smallmatrix} \right\} \cdot 2NH^4Cl + H^2O$ is obtained in large colourless crystals, which give off their water at 100° , and half their sulphurous acid as H^2SO^3 at 150° . The compound $Pt(SO^3H)^2$ is doubtless a bibasic acid, but its salts have not yet been examined (Birnbaum, *Zeitschr. f. Chem.* [2] v. 504).

Uranic Double Sulphites are obtained by passing sulphurous oxide into water in which uranic hydrate is suspended till a clear solution is obtained; concentrating this solution (which deposits uranic sulphite when heated), and mixing the filtrate with a strongly acid solution of potassium, sodium, or ammonium sulphite. The double salts then separate for the most part, and completely at a gentle heat, as yellow crystalline precipitates, which must be quickly collected on a filter, pressed, and dried over sulphuric acid and quick lime. When thus dried, they contain 1 or 2 mol. water, which they do not give up below the temperature at which they decompose. In the

hypothetically anhydrous state they have the composition U^MHSO^3 or $(U^M SO^3)^n \cdot OM$
 $\left. \begin{matrix} SO^3 \\ HM \end{matrix} \right\} OM$

[M = K, Na, or NH⁺]. The sodium salt is the only one that is moderately soluble in water; in aqueous sulphurous acid they dissolve more freely, the sodium salt being the most, and the potassium salt the least soluble. The precipitate, commonly regarded as uranic sulphite, which is thrown down from uranic salts by ammonium sulphite at the boiling heat, appears to consist of ammonio-uranic sulphite (Scheller, *Ann. Ch. Pharm.* cxliv. 238).

Ethylsulphurous and *Ethersulphurous Acids*. $C^2H^5SO^3$.—Ethylsulphurous acid is the acid produced by oxidising mercaptan or ethyl sulphocyanate with nitric acid (v. 553); ethersulphurous acid by the action of potash-ley on neutral ethyl sulphite at a low temperature. The constitution of these two acids and their derivation from sulphurous acid are represented by Wurtz (*Ann. Ch. Phys.* [4] xii. 494) as follows:

To prepare ethersulphurous acid, Warlitz (*Ann. Ch. Pharm.* cxliii. 72) adds potassium hydrate dissolved in 5 pts. of water, in successive quantities, to an equivalent quantity of neutral ethyl sulphite; leaves the mixture to itself for several days till the supernatant layer of ethyl sulphite has disappeared; then saturates the liquid with carbonic acid; evaporates it to dryness in a vacuum; and treats the residue while warm with alcohol of 90 p. c. The potassium salt of ethersulphurous acid which remains after evaporating the alcoholic solution is pure after recrystallisation from absolute alcohol. It dissolves easily in water and in hot alcohol of 90 p. c., rather slowly in boiling absolute alcohol, and crystallises therefrom in soft scales having a satiny lustre. When recently prepared it is inodorous, but after some time it gives off the odour of ethyl sulphide, and the aqueous solution then contains a sulphate. When heated it carbonises more easily than the isomeric potassium ethylsulphite, giving off vapours of volatile sulphur-compounds having a peculiar odour. Heated with strong sulphuric acid, it decomposes at a temperature at which the ethyl sulphite remains unaltered, depositing drops of oil and emitting the odour of mercaptan. The vapours turn iodised starch-paper blue. Mixed with potassium cyanide it gives off the odour of ethyl cyanide, which is not the case with the ethyl sulphite (Warlitz).

According to Graebe (*Ann. Ch. Pharm.* cxlvi. 37), the potassium salt of ethylsulphurous acid is produced by the action of ethyl iodide on potassium sulphite. This reaction—which is general with the chlorides and iodides of the alcohol-radicles—is represented by the equation:

3. Sulphuric Compounds.

SULPHURIC ACID and **ANHYDRIDE**. Sulphuric anhydride heated to 100° with carbon tetrachloride forms pyrosulphuric chloride, $S^2O^3Cl^2$ (p. 1070). With chloroform it reacts at ordinary temperatures, yielding carbon monoxide, pyrosulphuric chloride, and sulphuric chlorhydrate; similarly with bromine. When sulphuric anhydride and carbon bisulphide in nearly equivalent quantities are heated together on the water-bath, gas is given off, which, when freed from sulphurous anhydride and carbon bisulphide, consists of carbon oxysulphide (p. 406); the residue consists of pure sulphur (Armstrong, *Deut. chem. Ges. Ber.* ii. 712; *Zeitschr. f. Chem.* [2] vi. 247).

The compound $2\text{SO}^2 \cdot \text{N}^2\text{O}^2$ (r. 570) is formed directly by passing a series of induction-sparks through a mixture of oxygen, nitrogen, and sulphurous oxide, and collects on the sides of the vessel as a snowy crystalline mass (Marren, *Ann. Ch. Phys.* [4] iv. 800); also by passing a mixture of sulphurous oxide and nitrogen tetroxide through a strongly heated glass tube, or by passing sulphurous oxide over strongly heated lead nitrate (Weber, *Pogg. Ann.* cxxvii. 543).

The formation of sulphuric acid in the ordinary leaden-chamber process is effected, to Weber, chiefly by the oxidising action of nitrous acid (produced by the action of nitrogen dioxide or by decomposition of the tetroxide). Pure nitric acid oxidises sulphurous acid, excepting in presence of a considerable quantity of sulphuric acid (Weber, *loc. cit.*; also *Jahresb.* 1866, p. 127).

Vertraet (*Dingl. pol. J.* clxxix. 63) proposes to replace the leaden chambers by a series of bottomless stone-ware vessels filled with coke and placed one above the other. Tardani a. Susini (*Bull. Soc. Chim.* [2] viii. 295) have patented a process in which the burning of the sulphur and the oxidation of the sulphurous acid take place in condensed air, and small leaden chambers are used having a capacity of about 3 cubic metres.

Sprengel (*Chem. Soc. J.* [2] iv. 455) has invented an apparatus, consisting of a graduated glass tube with a caoutchouc piston, for gauging the depth of liquid on the floor of the leaden chambers, and for withdrawing a sample of all the heterogeneous layers of liquid for determining the mean specific gravity.

The presence of sulphurous acid and of the lower oxides of nitrogen in ordinary sulphuric acid may be detected by half-filling a stoppered flask with it, and introducing into the upper part of the vessel a strip of paper impregnated with iodine and starch, which will be bleached if sulphurous acid is present, or a strip impregnated with potassium iodide and starch, which will be turned blue if the liquid contains any of the lower oxides of nitrogen. Both these impurities may be detected together, unless the sulphurous acid is in great excess (R. Warington, *Chem. News*, xvii. 75).

The heat-capacities of sulphuric acid and its hydrates have been found by L. Pfandler (*J. pr. Chem.* ci. 507) to be as follows:

						Heat-capacity
SH^2O^4	.	between	77°	and	13°	0.3413
"	.	"	98°	"	16°	0.3542
"	.	"	137°	"	15°	0.3740
$\text{SH}^2\text{O}^4 \cdot \text{H}^2\text{O}$.	"	75°	"	14°	0.4478
"	.	"	98°	"	18°	0.4527
$\text{RH}^2\text{O}^4 \cdot 2\text{H}^2\text{O}$.	"	70°	"	14°	0.4703
"	.	"	98°	"	16°	0.4703

Hence it appears: 1. That the heat-capacity increases with the proportion of water and with the temperature.—2. That the change of capacity with the temperature is greatest in pure hydrogen sulphate, and diminishes very quickly in the hydrates.

Marignac showed some years ago (*Ann. Ch. Phys.* [3] xxxix. 184) that sulphuric acid of any strength ($\text{H}^2\text{SO}^4 + x\text{H}^2\text{O}$ as well as $\text{H}^2\text{SO}^4 + x\text{SO}^2$) leaves when boiled down, not pure hydrogen sulphate, H^2SO^4 , but a liquid having the composition $\text{H}^2\text{SO}^4 \cdot \frac{1}{12}\text{H}^2\text{O}$ or $\text{SO}^2 \cdot \frac{1}{12}\text{H}^2\text{O}$; and that the only way of obtaining the pure compound H^2SO^4 —besides direct combination of SO^2 and H^2O —is to expose oil of vitriol having as nearly as possible this composition to a very low temperature, whereupon the pure compound H^2SO^4 separates in crystals, the small excess of SO^2 or H^2O remaining in the mother-liquor. The crystals melt at 10.5° , the liquid heated to 30° – 40° gives off vapours of SO^2 , and when boiled is soon reduced to $\text{H}^2\text{SO}^4 \cdot \frac{1}{12}\text{H}^2\text{O}$.

In accordance with these results, it has been lately shown by Dittmar (*Chem. Soc. J.* [2] vii. 446) that when sulphuric acid, containing 99.5 p. c. of H^2SO^4 (prepared by mixing pure distilled oil of vitriol with the anhydride), is distilled under various pressures ranging from 3 to 314 centimetres of mercury, the residues are almost identical in composition with Marignac's hydrate, $\text{H}^2\text{SO}^4 \cdot \frac{1}{12}\text{H}^2\text{O}$; in other words, sulphuric acid, when boiled down under any pressure between these limits, behaves almost like a mixture of this stable hydrate with sulphuric anhydride. To account for this phenomenon, it is not, however, necessary to assume the existence of a stable molecule having the composition $12\text{SO}^2 \cdot 13\text{H}^2\text{O}$. It is known that hydrogen sulphate, H^2SO^4 , in the state of vapour, consists chiefly, and above certain temperatures entirely, of isolated molecules of SO^2 and H^2O (ii. 817). Now it may be assumed that in liquid sulphuric acid, even at low temperatures, some of the molecules have already assumed the state of motion corresponding to a temperature beyond that of dissociation (i. 866; iii. 133). The higher the temperature, the greater will be the

ratio of the number of the dissociated molecules to that of the unchanged ones.* The liberated molecules of H_2O and SO^2 , being formed in the midst of a mass of molecules of H^2SO^4 , will probably mostly unite with comparatively cold molecules of H^2SO^4 , forming compounds represented by $\text{H}^2\text{SO}^4 \cdot 2\text{H}^2\text{O}$ and $\text{H}^2\text{SO}^4 \cdot 2\text{SO}^2$ respectively. Assuming now that the latter compounds are less stable than the former, it is easy to understand that in the distillation of sulphuric acid, the anhydride SO^2 (compared with $\text{SO}^2 \cdot \text{H}^2\text{O}$) will predominate in the vapour, and in a greater degree, the higher the temperature, i.e. the greater the pressure under which the liquid boils (Dittmar, also Pfaundler (*Zeitschr. f. Chem.* [2] vi. 66).

SULPHURIC CHLORHYDRATE. $\text{HClSO}^2 = \text{SO}^2 \begin{cases} \text{Cl} \\ \text{OH} \end{cases}$ — Williamson. This compound is obtained by distilling strong sulphuric acid with phosphorus pentachloride (v. 576). According to S. Williams (*Chem. Soc. J.* [2] vii. 304), if an excess of sulphuric acid is used in this process, only a small quantity of the chlorhydrate is obtained. As soon as this is distilled off, sulphuric anhydride passes over, and afterwards, at a higher temperature, tabular crystals collect in the neck of the retort, probably consisting of a definite hydrate of sulphuric acid. Afterwards sulphuric acid distils over, and metaphosphoric acid remains behind. In neither of these distillates was phosphoric acid found after addition of water. Hence it follows that the phosphorus oxychloride formed in the first instance (v. 576) acts further on the sulphuric acid in a manner which may be represented by the equations:

and

The greatest amount of sulphuric chlorhydrate is obtained when 3 mol. sulphuric acid are used to 1 mol. of the pentachloride, so as to ensure complete decomposition of the oxychloride. In this case the entire reaction is:

If a very large excess of sulphuric acid is used, no sulphuric chlorhydrate is obtained, but hydrochloric acid in large quantity, and sulphuric anhydride, because Nordhausen sulphuric acid is formed by the action of the chlorhydrate on the sulphuric acid:

The vapour-density of the chlorhydrate, referred to hydrogen, was found by Dumas' method at 216° to be 32.857, which corresponds to a condensation to $\frac{1}{3}$ volumes. Hence it appears probable that the compound when vaporised is resolved into HCl and SO^2 .

Dewar & Cranston (*Chem. News*, xx. 174) prepare sulphuric chlorhydrate by the direct action of hydrochloric acid gas on sulphuric acid containing a large quantity of anhydride in solution; the action is very rapid and the temperature rises to 120° . The chlorhydrate heated to 100° in a sealed tube with carbon bisulphide, forms carbon oxy sulphide, hydrochloric acid, and sulphurous anhydride:

Sulphuric chlorhydrate acts violently on many organic compounds. With 1 mol. ethyl alcohol it forms a black tarry mass, which becomes very hot in contact with water, and gives off a gas which attacks the mucous membranes. With 2 mol. alcohol, the residue is a thickish liquid, from which water dissolves ethyl-sulphuric acid and separates oily neutral ethyl sulphate. With pure ethyl oxide, it likewise forms neutral ethyl sulphate. Heated to 140° with $\frac{1}{2}$ mol. acetic acid, it forms glycol sulphurous acid, $\text{C}^2\text{H}^2\text{SO}^3$. With butyric acid it yields disulphopropionic acid, $\text{C}^2\text{H}^2\text{SO}^3$. One mol. acetic anhydride and 2 mol. sulphuric chlorhydrate, heated to 160° in a stream of carbon dioxide, yield an acid, $\text{C}^2\text{H}^2\text{SO}^2$, which, when separated from its lead salt and evaporated in a vacuum, remains as a deliquescent crystalline mass insoluble in alcohol and ether. The lead salt, $\text{C}^2\text{H}^2\text{PbSO}^2$, crystallises in white prisms (Baumstark, *Ann. Ch. Pharm.* xli. 75; *Jahresh.* 1866, p. 284). The chlorhydrate acts very strongly on ethyl iodide, forming ethylsulphurous acid. With ethylene bromide it forms an acid having the composition $\text{C}^2\text{H}^2\text{Br} \cdot \text{SO}^2\text{H}$ (Wroblevsky, *Zeitschr. f. Chem.* [2] v. 280). With benzene it forms sulphobenzene, together with phenyl-sulphurous acid and phenyl-sulphurous chloride (Knapp, *ibid.* 41):

The corresponding compound *sulphuric chlorethylate*, $\text{SO}^2\text{Cl}(\text{OC}^2\text{H}^5)$, produced by direct combination of SO^2 and $\text{O}^2\text{H}^5\text{Cl}$, was discovered by R. Williamson in 1857 (v. 576), and has lately been further examined by Purgold (*Compt. rend.* lxxvii. 451; *Ann. Ch. Pharm.* cxlix. 124), who seems to be quite unacquainted with Williamson's experiments. It is a pungent, oily, strongly refracting liquid, having a sp. gr. of 1.3790 at 0° ; 1.3556 at 27° ; 1.3240 at 61° . Expansion-coefficient = 0.0006393 between 0° and 27° , and 0.007155 between 27° and 61° . Heated to 100° with water in a sealed tube, it yields sulphuric acid, hydrochloric acid, ethyl iodide, and a little ethyl chloride; with alcohol, a similar reaction, but the hydrochloric acid and the alcohol reproduce ethyl chloride. With a concentrated solution of sodium acetate, it yields ethyl acetate, sodium sulphate, and free acetic acid:

When liquid ethyl chloride is agitated with sulphuric anhydride in a sealed tube, and the product is treated with water, an acid, $\text{C}^2\text{H}^5(\text{OH})(\text{OH})(\text{SO}^2)^2$, is formed, the potassium salt of which crystallises in beautiful white needles (Purgold).

Chlorosulphuric Anhydride or *Pyrosulphuric Chloride*. $\text{S}^2\text{O}^3\text{Cl}^2$.—This compound, which Rose obtained by the action of sulphuric anhydride on sulphur chloride, S^2Cl^2 (v. 571), is likewise produced, together with phosgene, by dissolving the anhydride in excess of carbon tetrachloride, and heating the solution in the water-bath:

If the mixture of sulphuric anhydride and carbon tetrachloride be heated to 100° with benzene, and the product treated with water, it yields hydrochloric acid, sulphobenzene, phenylsulphurous acid, and benzoic acid (Schützenberger, *Zeitschr. f. Chem.* [2] v. 631).

Pyrosulphuric chloride is also formed, together with sulphuric chlorhydrate and carbon monoxide, by the action of sulphuric anhydride on chloroform. It boils at 144° – 148° . The corresponding bromide is obtained in like manner with bromoform (Armstrong, *Zeitschr. f. Chem.* [2] vi. 247).

METALLIC SULPHATES. *Aluminium Sulphate*.—On the preparation and testing of this salt for technical purposes, see Fleck (*J. pr. Chem.* xcix. 243; *Bull. Soc. Chim.* [2] viii. 39); Stein (*Zeitschr. anal. Chem.* v. 35); Gieseke (*Dingl. pol. J.* clxxxiii. 43; *Bull. Soc. Chim.* [2] vii. 361; *Jahresb.* 1866, pp. 788, 856; 1867, p. 910).

Barium Sulphates.—The normal salt dissolves abundantly in hydrogen sulphate, H^2SO^4 , at the boiling heat, especially when recently precipitated (100 pts. of the acid dissolve 11 to 12 pts. barium carbonate); the saturated solution does not deposit anything on cooling, but on evaporation yields the normal salt in crystalline granules. At 100° , normal barium sulphate dissolves still more easily in the strong acid, the solution becoming turbid at a higher temperature and depositing a white powder. On digesting the acid at a somewhat higher temperature with excess of the normal salt, *anhydrous acid barium sulphate*, $\text{BaH}^2(\text{SO}^4)^2$ or $\text{BaSO}^4 \cdot 2\text{H}^2\text{SO}^4$, crystallises out in delicate shining prisms. When the solution of the normal salt in strong sulphuric acid is exposed to moist air, it deposits the *hydrated acid salt*, $\text{BaH}^2(\text{SO}^4)^2 \cdot 2\text{H}^2\text{O}$, in slender soft asbestos-like needles (Schultz).

Bismuth Sulphates.—*Bismuth-ammonium Sulphate*, $\text{Bi}^3(\text{NH}^4)(\text{SO}^4)^2 + 4\text{H}^2\text{O}$, is prepared by adding a strong solution of acid ammonium sulphate to a solution of 109 pts. bismuth in 100 pts. nitric acid (3 mol. of the acid ammonium sulphate to 1 mol. bismuth nitrate), and separating the crystalline precipitate from the mother-liquor by pressure between filter-paper. It crystallises in six-sided tables, dissolves easily in hydrochloric and in nitric acid, less easily in strong sulphuric acid and in hot dilute acids. By prolonged digestion with cold acetic or dilute sulphuric acid it is resolved into acid ammonium sulphate and *bismuth-hydrogen sulphate* or *acid bismuth sulphate*, $\text{Bi}^3\text{H}(\text{SO}^4)^2 + \text{H}^2\text{O}$, which latter partly dissolves and separates from the solution on warming in microscopic needles, partly remains as an insoluble residue. Both this salt and the ammonium double salt are decomposed by prolonged boiling with water, leaving the monoacid salt $\text{SO}^2 \cdot \text{Bi}^3 \cdot \text{O}^2$, or *bismuth oxyulphate*, $\text{Bi}^3 \left\{ \begin{matrix} \text{SO}^4 \\ \text{O}^2 \end{matrix} \right.$.

Bismuth-sodium sulphate, prepared like the ammonium salt, separates immediately as a crystalline precipitate made up of groups of microscopic needles. Its composition, neglecting a small and variable amount of water, is approximately represented by the formula $\text{Bi}^3\text{Na}^3(\text{SO}^4)^6$, and differs therefore both from that of the ammonium

salt, and from that of the potassium salt, $\text{BiK}^*(\text{SO}^*)$ (Lüddeke, *Ann. Ch. Pharm.* 277).

A tetrammonio-cadmium sulphate, $\text{SO}^*\text{Cd}.4\text{NH}^*$, is obtained by mixing cadmium sulphate with a quantity of strong ammonia sufficient to redissolve the precipitate first produced, then adding a double volume of absolute alcohol containing ammonia, and agitating. A thick liquid then separates, which, after being shaken with the supernatant solution, solidifies in a few days to a crystalline powder. On separating this powder from the liquid, redissolving it in strong aqueous ammonia, and covering the solution, with ammoniacal alcohol, the salt $\text{SO}^*\text{Cd}.4\text{NH}^* + 6\text{H}^*\text{O}$ is deposited in a few days in short hexagonal prisms with predominant perpendicular end-face, sometimes also with a di-hexahedron of another order; cleavable parallel to the perpendicular end-face. They give off ammonia, and crumble to a white powder on exposure to the air, dissolve easily in ammonia and in hydrochloric acid, and are decomposed by water, with separation of a flocculent gelatinous precipitate, while ammonium sulphate passes into solution (G. Müller, *Ann. Ch. Pharm.* cxlix. 70).

Calcium Sulphates.—Pulverised gypsum heated with water in sealed tubes to 140° – 160° is converted into a coherent crystalline mass of the salt $2\text{CaSO}^*.\text{H}^*\text{O}$, which is not altered by prolonged heating, but is reconverted into gypsum in the cold. If the water be replaced by a saturated solution of sodium chloride (by enclosing pieces of rock-salt in the tube) the gypsum crystals are converted at 125° – 130° into a milk-white porcelain-like mass, consisting of interlaced crystals of anhydrite, which is also reconverted into gypsum in the cold. At comparatively high temperatures, therefore, solution of sodium chloride (and calcium chloride more slowly) withdraws water from gypsum, but at ordinary temperatures anhydrite takes water from a solution of sodium chloride. Consequently gypsum dehydrated at 126° hardens in contact with solution of sodium chloride. This reaction may perhaps explain the occurrence of masses of anhydrite in beds of rock-salt (Hoppe-Seyler, *Pogg. Ann.* cxxvii. 161). When an aqueous solution of gypsum and magnesium bicarbonate is evaporated, the calcium sulphate, in consequence of the decomposition of the latter, is likewise decomposed, forming calcium carbonate and magnesium sulphate. If, however, the evaporation takes place at ordinary temperatures in an atmosphere containing carbonic acid, the calcium sulphate crystallises from such solutions without alteration. This may account for the association of gypsum with dolomite (T. S. Hunt, *Bull. Soc. Chim.* [2] viii. 181). From experiments with pure native gypsum, Church (*ibid.* ix. 308) finds that 1 pt. of $\text{CaSO}^*.\text{H}^*\text{O}$ dissolves in 443 pts. water at 13.7° , in 447 pts. at 14.2° , in 421 pts. at 20.2° , in 419 pts. at 21.2° , and at 18.7° in 445 pts. water saturated with carbonic acid.—Boiling concentrated sulphuric acid dissolves about ten times its weight of normal calcium sulphate, and the solution when evaporated, first yields granular anhydrous crystals of the normal salt, and afterwards solidifies to a mass of flat silky prisms of the salt $\text{CaH}^*(\text{SO}^*)$ or $\text{CaSO}^*.\text{H}^*\text{H}^*\text{SO}^*$. This salt melts at a little above 100° to a white pasty magma, probably with formation of the acid salt described by Berzelius (Schultz, *Pogg. Ann.* cxxxiii. 137).

Cobalt Sulphate.—When a concentrated solution of this salt is gradually poured into ordinary sulphuric acid, a peach-blossom-coloured pulverulent precipitate soon separates, having the composition $\text{CoSO}^*.\text{H}^*\text{O}$ (Fröhde, *J. pr. Chem.* xcix. 63).

Copper Sulphates.—On the solubility of normal cupric sulphate in water, see Dineen (*Jahresb.* 1866, p. 63); Gerlach (*ibid.* 129). On its efflorescence: Pape (*ibid.* 1867, p. 2). On the refracting power of its solution: Fouqué (*ibid.* 97).

Normal cupric sulphate dissolves but sparingly in boiling concentrated sulphuric acid, and crystallises out again on evaporation or on cooling, as anhydrous salt. From a solution not saturated at the boiling heat, an acid salt appears to separate on cooling (Schultz).

Basic Salts.—According to Reindel (*J. pr. Chem.* c. i), the pale green basic salt precipitated by the potash from excess of cupric sulphate at the boiling heat or at 40° – 50° , has the composition $7\text{CuO}.2\text{SO}^* + 7\text{H}^*\text{O}$ or $2\text{CuSO}^*.\text{H}^*\text{O} + 7\text{H}^*\text{O}$. The same salt is formed when potassio-cupric sulphate is repeatedly washed with hot water; also by digesting cupric oxide precipitated at the boiling heat with a solution of cupric sulphate: the oxide prepared by igniting the nitrate remains unaltered when thus treated. The blue-green precipitate is not attacked by boiling water or by boiling solutions of cupric sulphate; but it dissolves easily in acids and is converted by potash into the black hydrate $3\text{CuO}.\text{H}^*\text{O}$. It does not lose water at 100° , but is converted at 150° into the pentahydrate $2\text{CuSO}^*.\text{H}^*\text{O} + 5\text{H}^*\text{O}$, and decomposes at a higher temperature, leaving a residue from which boiling water extracts the normal salt. The blue-green precipitate thrown down from excess of cupric sulphate by ammonia at the boiling heat has, according to Reindel, the composition $6\text{CuO}.2\text{SO}^* + 5\text{H}^*\text{O}$ or $2(\text{CuSO}^*.\text{H}^*\text{O}).\text{H}^*\text{O}$. It remains unaltered at 250° , but decomposes

at a higher temperature, like the preceding salt. Sodium carbonate under the same circumstances throws down a pale green sulphate consisting of $3\text{CuO} \cdot \text{SO}^2 + 2\text{H}^2\text{O}$ or $\text{CuSO}^4 \cdot 2\text{CuO} + 2\text{H}^2\text{O}$. This compound, which remains unaltered up to 270° , appears to be likewise produced by prolonged boiling of zinc oxide with a solution of cupric sulphate. None of these basic salts give up the whole of their sulphuric acid even on prolonged ignition.

Indium Sulphate.—See INDIUM (p. 732).

Iron Sulphates.—On the specific gravity of solutions of ferrous sulphate, see Gerlach (*Jahresb.* 1866, p. 128). F. Muck (*J. pr. Chem.* xcix. 103; *Jahresb.* 1866, p. 241) has examined the alterations which take place in solutions of ferrous sulphate on exposure to the air. He finds that in the earlier stages of the oxidation the solution contains normal ferric sulphate, $\text{Fe}^2\text{O}^3 \cdot 3\text{SO}^4$, and even free sulphuric acid, but ultimately the basic salt $\text{Fe}^2\text{O}^3 \cdot 2\text{SO}^4$, distinguished by its deep brown-red colour. At the same time the deposit becomes progressively richer in acid, without, however, attaining the composition $2\text{Fe}^2\text{O}^3 \cdot 3\text{SO}^4$, assigned to it by Wittstein (v. 595). The products of the oxidation vary with the continually changing composition of the solution, and cannot therefore be reduced to any simple expression. The basic ferric sulphates occurring as natural products are partly precipitates of this kind, partly dried-up mother-liquors.

Lead Sulphates.—According to Boussingault (*Compt. rend.* lxiv. 1159) normal lead sulphate is completely resolved at a white heat into PbO and SO^4 . According to Rodwell (*Chem. News*, xv. 137), the same salt heated to redness in a current of dry ammonia gas is decomposed in the manner represented by the equation:

100 pts. of strong sulphuric acid dissolve about 6 pts. of normal lead sulphate, and a hot-saturated solution left to cool deposits the same salt in shining laminae; but by slow evaporation in moist air a hydrated acid salt, $\text{PbH}^2(\text{SO}^4)^2 + \text{H}^2\text{O}$, is obtained (Schultz).

Lithium Sulphates.—On the crystalline forms of normal lithium sulphate, lithio-potassic and lithio-sodic sulphate, see LITHIUM (p. 792). *Acid lithium sulphate*, LiHSO^4 , crystallises in prisms from a solution of the normal salt in sulphuric acid of sp. gr. 1.6 to 1.7 (from more dilute acid, the normal salt separates again). The acid salt melts at 160° (Schultz).

Magnesium Sulphates.—The extraction of the normal salt from the mother-liquors of the salt-gardens at Camargue is described by Balard (*Bull. Soc. d'Encouragement*, 1865, xii.; *J. Pharm.* [4] iii. 179; *Jahresb.* 1866, p. 847). On the preparation of this salt, see also Mirus (*N. Jahrb. Pharm.* xxvii. 92) and Swindells (*Chem. News*, xv. 178). It dissolves but slightly in boiling hydrogen sulphate, H^2SO^4 (2 pts. in 100 pts. of the acid), more abundantly in acid of sp. gr. 1.7, and this solution when cooled or further evaporated at the boiling heat, deposits the acid salt, $\text{MgH}^2(\text{SO}^4)^2$ or $\text{MgSO}^4 \cdot \text{H}^2\text{SO}^4$, in prisms differing by their infusibility from the following salt. The *triacid salt*, $\text{MgH}^3(\text{SO}^4)^4$ or $\text{MgSO}^4 \cdot 3\text{H}^2\text{SO}^4$, crystallises on cooling from a solution of the normal salt in boiling hydrogen sulphate, in small shining tables which partly melt and decompose when heated (Schultz).

Manganese Sulphates.—The normal salt dissolves in about 20 pts. of boiling hydrogen sulphate, and the solution on beginning to cool deposits the *acid salt*, $\text{MnH}^2(\text{SO}^4)^2$, in asbestiform prisms, which do not melt when heated; they are generally, however, mixed with the hexhydromanganous salt, $\text{MnH}^6(\text{SO}^4)^4$, which separates from the same solution below 100° in small crystalline laminae melting with decomposition when heated. Sulphuric acid of sp. gr. 1.6 dissolves the normal salt more readily when heated, and the solution on cooling deposits the hydrated acid salt, $\text{MnH}^2(\text{SO}^4)^2 + \text{H}^2\text{O}$, in nacrous laminae.

Potassium Sulphates.—On the solubility of the normal salt, see *Jahresb.* 1866, pp. 59, 67. The *trihydropotassic* or *hyperacid salt*, $\text{KH}^3(\text{SO}^4)^2$ or $\text{KHSO}^4 \cdot \text{H}^2\text{SO}^4$, is formed by fusing the normal salt with less than 3 mol. hydrogen sulphate: the mixture solidifies after a while to a crystalline cake, consisting for the most part of this hyperacid salt. It is obtained in isolated crystals when the solution of the normal salt in less than 5 mol. hydrogen sulphate is made to crystallise by introducing into it a granule of the solidified mass. It crystallises in long shining prisms melting at about 95° . It does not solidify from fusion even when cooled to a low temperature, but it solidifies, with considerable rise of temperature, when brought in contact with a crystal of the solid hyperacid salt, but not by contact with a crystal of the normal or acid salt (Schultz).

Silver Sulphates.—The acid salt, or *hydro-argentic sulphate*, AgHSO_4 , crystallises in faintly yellowish prisms from a solution of the normal salt in less than three parts of hydrogen sulphate. A solution of the normal salt in 8 or 10 pts. acid of sp. gr. 1.6 to 1.7 yields *trihydro-argentic sulphate*, $\text{AgH}_3(\text{SO}_4)_3 + \text{H}_2\text{O}$, in prisms. Larger crystals of this salt are obtained by dissolving the normal salt in 6 to 10 pts. hydrogen sulphate, and leaving the solution to become diluted by exposure to moist air. The salt begins to melt at 100° , becomes perfectly fluid at 150° , and solidifies on cooling to a broadly laminar crystalline mass, gradually changing into small, flat, shining prisms. A warm solution of the normal salt in only 4 to 6 pts. of acid of sp. gr. 1.75 deposits on cooling the *hexhydro-tetrargentic salt*, $\text{Ag}_4\text{H}_4(\text{SO}_4)_6 + 2\text{H}_2\text{O}$, in nacreous laminæ. Other silver sulphates appear also to separate from variously concentrated solutions in sulphuric acid, but their preparation does not always succeed. The normal salt, Ag_2SO_4 , likewise crystallises in yellowish rhombic octohedrons from a cooled solution in somewhat diluted sulphuric acid, or in the more concentrated acid when the liquid is left to absorb water gradually from the air (Schultz).

Trihydro-sodic Sulphate, $\text{NaH}_3(\text{SO}_4)_3$, crystallises on cooling from a hot-prepared solution of the normal sodium salt in less than 7 pts. of hydrogen sulphate; it resembles the corresponding potassium salt, and melts at about 100° .

Strontium Sulphates.—According to Boussingault (*Jahresb.* 1867, p. 161) the normal salt is decomposed at a full white heat into SrO and SO_2 . According to Darmstadt (*ibid.* 152) it is partially decomposed at lower temperatures. An earthy mineral containing 86 p. c. of this salt (together with lime, magnesia, clay, &c.) occurs in Upper Silesia, where it is used as a manure, like gypsum (Lunge, *Chem. News*, xv. 218). The *anhydrous acid salt* and the *hydrated acid salt*, $\text{SrH}_2(\text{SO}_4)_2 + \text{H}_2\text{O}$, are prepared like the corresponding barium salts (Schultz).

Thallium Sulphates.—The normal thallous salt, Tl_2SO_4 , may be fused without alteration in a covered crucible at the volatilising temperature of common salt; heated in an open vessel, or by the blowpipe-flame, it is decomposed, with evolution of sulphurous oxide and formation of thallous oxide, Tl_2O_3 . Ignited in a current of hydrogen, it melts, blackens, gives off sulphur, and finally leaves a mixture of metallic thallium, thallium sulphide, and thallous sulphate. An acid salt is precipitated by water from a solution of thallium in strong sulphuric acid, as an amorphous powder, the aqueous solution of which first yields crystals of the normal salt, and afterwards thick short prisms of the acid salt (Carstanjen, *Jahresb.* 1867, p. 279).

Titanium Sulphates.—See TITANIUM.

Zinc Sulphates.—According to Reindel (*Zeitschr. f. Chem.* [2] v. 508) the precipitate formed by boiling zinc sulphate with ammonia has, when washed with water and dried over oil of vitriol, the composition $8\text{ZnO} \cdot 16\text{H}^2\text{O} \cdot \text{SO}_2$; at 110° , $8\text{ZnO} \cdot 7\text{H}^2\text{O} \cdot \text{SO}_2$; at 200° , $8\text{ZnO} \cdot 6\text{H}^2\text{O} \cdot \text{SO}_2$; at 250° , $8\text{ZnO} \cdot \text{H}^2\text{O} \cdot \text{SO}_2$. This last salt yielded to cold water considerable quantities of the normal sulphate, $\text{ZnO} \cdot \text{SO}_2$. It does not appear, however, to be a mixture of normal sulphate and zinc hydrate; for even after washing for six weeks with hot water it did not yield a residue free from sulphuric acid. The basic salt remaining after this treatment had when dried at 100° the composition $9\text{ZnO} \cdot 12\text{H}^2\text{O} \cdot \text{SO}_2$.

An ammoniacal zinc sulphate, $\text{SO}_4\text{Zn} \cdot 4\text{NH}_3 + 2\text{H}_2\text{O}$, prepared like the corresponding cadmium salt (p. 1071), separates as a syrup which gradually changes to a crystalline powder. At a winter temperature the solution yields crystals of another hydrate, $\text{SO}_4\text{Zn} \cdot 4\text{NH}_3 + 4\text{H}_2\text{O}$, which effloresces in the cold to a white powder, with continual evolution of ammonia, and deliquesces on the slightest rise of temperature (G. Müller, *Zeitschr. f. Chem.* [2] v. 250; vi. 96).

4. Thiosulphuric Acid. $\text{H}_2\text{S}^2\text{O}_3 = \begin{matrix} \text{HS} \\ \text{HO} \end{matrix} \{ \text{SO}_2$.—This is the acid commonly called hyposulphurous acid, produced by sulphuration of sulphurous acid, just as sulphuric acid is formed by oxidation of the latter. By some chemists, however, as already stated (v. 630), it has been represented by the simpler formula H_2SO_2 , and regarded as a monobasic acid analogous to formic acid, H^2CO_2 , this view being based partly on its supposed formation by the reducing action of zinc, sodium, and other metals on sulphurous acid, partly on a statement of Rose that all hyposulphites contain water, which appears to be essential to their constitution, since it cannot be driven off without further decomposition; and, such being the case, the ordinary formula of a hyposulphite admits of being halved: e.g. $\text{Na}_2\text{S}^2\text{O}_3 \cdot \text{H}_2\text{O} = \text{Na}_2\text{H}^2\text{SO}_4 = 2\text{NaHSO}_2$. Pape, however, showed in 1864 that the lead salt of this acid contains no water of crystallisation, and when dried at 100° has the composition $\text{Pb}_2\text{S}^2\text{O}_3$; moreover that potassium, sodium, and barium salts give off their water at about 215° , and decompose with separation of sulphur between 220° and 225° . These experiments of Pape

Sup.

3 Z

do not appear to have been much noticed, and the representation of the acid in question by the formula H^2SO^2 was advocated by Dupré in 1867 (*Chem. Soc. J.* [2] v. 295), and in 1869 by Odling (*ibid.* vii. 180), the latter of whom regards it as a hydracid having the constitution $\begin{smallmatrix} \text{H} \\ \text{H} \end{smallmatrix} \text{SO}^2$. This view was suggested by the observation of Stokes (*ibid.* 174) that the fluorescence of quinine solutions is affected by hyposulphurous acid in the same manner as by hydrochloric acid and other hydracids (p. 786). On the other hand, Schorlemmer (*ibid.* 254), in recalling attention to the observations of Pape, has further pointed out that the tendency of the so-called hyposulphurous acid to split up into sulphurous acid and sulphur is most readily explained by supposing that its molecule contains two atoms of sulphur. In many of its reactions, indeed, it splits up in such a manner that the atom of sulphur previously contained in the sulphurous oxide remains in the oxidised state, whilst the other atom separates as free sulphur or as a sulphide; thus:

The question may now be regarded as completely set at rest by Schützenberger's recent discovery (p. 1063) that the acid H^2SO^2 produced by the action of zinc on sulphurous acid, is totally different from the acid produced by sulphuration of sulphurous acid. Schützenberger calls his acid *hydrosulphurous acid*; but it is more consistent with analogy to designate it as *hyposulphurous acid*, and the acid produced by sulphuration of sulphurous acid as *thiosulphuric acid*. The formula $\text{H}^2\text{S}^2\text{O}^3$ for the latter, is further corroborated by the existence of a *selenio-sulphuric acid*, presently to be described. These acids, together with sulphurous and sulphuric acid, form the following series:

Hypsulphurous acid . . .	H^2SO^2	$= \begin{smallmatrix} \text{H} \\ \text{H} \end{smallmatrix} \text{SO}^2$
Sulphurous acid . . .	H^2SO^3	$= \begin{smallmatrix} \text{H} \\ \text{HO} \end{smallmatrix} \text{SO}^2$
Sulphuric acid . . .	H^2SO^4	$= \begin{smallmatrix} \text{HO} \\ \text{HO} \end{smallmatrix} \text{SO}^2$
Thiosulphuric acid . . .	H^2SSO^3	$= \begin{smallmatrix} \text{HS} \\ \text{HO} \end{smallmatrix} \text{SO}^2$
Selenio-sulphuric acid . . .	H^2SeSO^3	$= \begin{smallmatrix} \text{HSe} \\ \text{HO} \end{smallmatrix} \text{SO}^2$

Test for Thiosulphuric Acid.—The smallest trace of a soluble thiosulphate may be detected by addition of ruthenium salt. When a solution of ruthenium rendered alkaline by ammonia is boiled with sodium thiosulphate, it gradually assumes a red colour, passing into a rich carmine; strong solutions become almost black; with only $\frac{1}{25000}$ of thiosulphate a rose-red colour is produced, and with $\frac{1}{250000}$ a pale-red colour. Conversely, a solution of sodium thiosulphate may be used as a test for ruthenium (Carey Lea, *Sill. Am. J.* [2] xlv. 222; *Chem. Centr.* 1870, p. 47).

Metallic Thiosulphates.—Sodium thiosulphate is recommended by Fröhde (*Zeitschr. f. Chem.* [2] ii. 543; *Zeitschr. anal. Chem.* v. 160; *Jahresh.* 1866, pp. 157, 765): 1. For the preparation of all metallic compounds which are usually obtained by fusion with an alkaline carbonate and sulphur.—2. As a reagent in various analytical processes, especially for the analysis of ferro- and ferri-cyanides (v. 631); for the separation of metals of the arsenic group from those of the lead group, the former being thereby converted into soluble sulphur-salts, while the latter remain insoluble in water; for the separation of the heavy metals from phosphoric acid, and of ferric oxide from alumina (as recommended long ago by Chancel, i. 155).—3. As a blowpipe reagent for the detection of the heavy metals. When heated with certain metallic salts it first produces peculiar colours (manganous salts being decolorised, cobalt salts coloured blue-green, molybdates brown-red, chromates green), afterwards the characteristic colour of the metallic sulphide, which disappears in the oxidising flame, and reappears on renewed addition of thiosulphate. Fröhde has also described a general course of quantitative analysis of insoluble compounds, consisting essentially in heating the dry substance with thiosulphate of sodium, barium, or ammonium, whereby the heavy metals are converted into sulphides, and the alkaline earths into sulphates.

Copper Salt.—When a solution of cuprous chloride in sodium thiosulphate is left to itself for six or eight days, then filtered from the precipitated copper sulphide, and mixed with excess of ammonia, the liquid becomes colourless, and glassy violet

rhombic crystals are formed, a further quantity of which is obtained on adding ammonia to the mother-liquor. They are nearly insoluble in cold water, and are decomposed by hot water, with evolution of ammonia and separation of brown flocks and a specular deposit on the glass; the cooled filtrate mixed with ammonia again yields blue crystals. These crystals have the composition $N^+H^{12}Na^+Cu^{+2}S^{2-}O_4^{12}$. Heated with potash-ley they yield a precipitate consisting of a cuproso-cupric hydrate, consisting when air-dried of $Cu^+O \cdot 2H^+O$, and after drying in a vacuum of $Cu^+O \cdot 2 \cdot H^+O$:

(Siewert, *Bull. Soc. Chim.* [2] vii. 242; *Jahresh.* 1866, p. 256). Compare v. 633.

Sodio-platinous Thiosulphate, $\text{Na}_4\text{Pt}(\text{S}_2\text{O}_3)_4 \cdot 10\text{H}_2\text{O}$, is obtained by adding pulverised crystals of ammonium platinochloride to a concentrated solution of potassium thiosulphate, mixing the yellow liquid with twice or three times its volume of absolute alcohol, separating the heavy oily layer, which gradually solidifies to crystalline mass, from the colourless liquid, dissolving it in a small quantity of water, and reprecipitating with alcohol, taking care to leave a portion of the salt in solution. By a third precipitation from the aqueous solution, and washing with absolute alcohol, the salt is obtained nearly pure. After drying over oil of vitriol, it forms a compact, yellow, partly brownish mass, which does not exhibit distinct crystals under the microscope. It dissolves easily in water. The solution is not altered by caustic potash or soda even at the boiling heat, slowly by hydrochloric acid in the cold, quickly when heated, with evolution of sulphurous oxide and precipitation of platinum sulphide. Hydrogen sulphide does not precipitate the platinum, either from the neutral or from the cold acidulated solution. The same double salt appears to be formed by dissolving ammonium platinochloride in sodium thiosulphate, but it cannot be isolated in this manner on account of the great instability of the resulting solution (Schötländer, *Ann. Ch. Pharm.* exl. 200). Its composition affords further and decisive confirmation of the bibasic character of thiosulphuric acid.

5. **Seleniosulphuric Acid.** $\text{H}^2\text{SeSO}_3 = \frac{\text{HSe}}{\text{HO}} \left\{ \text{SO}_2 \right.$ *Seleniohyposulphurous Acid.*

Selenodithionous Acid.—This acid, formed by addition of selenium to sulphurous acid, was first obtained as a potassium salt by Cloez (*Bull. Soc. Chim.* Dec. 13, 1861), and further examined by Kalko (*J. pr. Chem.* xev. i.; *Jahresb.* 1865, p. 144). When selenium is digested with a solution of neutral potassium sulphite, and the easily decomposable liquid, after being filtered from the selenium which separates on cooling and dilution with water, is left to evaporate at ordinary temperatures, there crystallises out, first a sparingly soluble seleniferous salt in small shining prisms, afterwards a much more soluble salt, which is the chief product of the reaction, while the excess of sulphite remains in the mother-liquor.

The more soluble seleniferous salt is potassium seleniosulphate, $K^+SeSO_4^-$. It is likewise formed, together with thiosulphate, when a solution of potassium selenide is mixed with sulphurous acid. It crystallises readily, even from small quantities of solution in large very thin six-sided tables belonging to the rhombic system, which deliquesce in moist air, and effloresce with partial loss of water over oil of vitriol. When heated they turn brown and yield a polysulphide of potassium. Water separates selenium from them, and the filtered solution yields by evaporation crystals which again react in the same way with water, so that by repeated crystallisation the whole of the seleniosulphate may be decomposed; the liquid then contains seleniotriethionate. *Acids*, even sulphurous acid, throw down the whole of the selenium from the aqueous solution; *barium chloride* and *baryta-water* precipitate barium sulphite and selenium; *calcium* and *manganese salts* give rise to a similar decomposition. With *ammoniacal silver solution* the seleniosulphate forms a precipitate of silver selenide together with potassium sulphate:

A neutral silver solution decomposes part of the acid at the same time into selenium and sulphurous acid. *Mercuric cyanide* at the boiling heat forms mercuric selenide and potassium sulphate; neutral *cadmium solutions* throw down white sparingly soluble cadmium seleniosulphate, which is resolved by heat into cadmium selenide and sulphuric acid. By digestion with recently precipitated *silver sulphide*, the seleniosulphate is easily and completely resolved into silver selenide and potassium thiosulphate. *Iodine* throws down selenium, which is oxidised by the excess of iodine. *Ferric chloride* throws down selenium, together with a brown precipitate containing iron.

The sulphites of sodium, ammonium, and magnesium react with selenium in the same manner as the potassium salt, the magnesium salt however very slowly. The selenio-sulphates of sodium and ammonium are very unstable (Rathke).

6. **Dithionie Acid.** $\text{H}_2\text{S}^2\text{O}^6$.—According to Otto (*Ann. Ch. Pharm.* cxlvii. 187) this acid is reduced by nascent hydrogen (either by prolonged contact of the solution of its barium salt with sodium-amalgam, or by the action of zinc and hydrochloric acid) to sulphurous acid, even when the mixture is cooled to 0° . On the crystalline form of *lithium dithionate*, see LITHIUM SALTS (p. 792).

7. **Trithionie Acid.** $\text{H}_2\text{S}^3\text{O}^6$ (v. 639).—According to Saintpierre (*Bull. Soc. Chim.* [2] v. 246) the formation of this acid by Langlois' method (digesting acid potassium sulphite with sulphur) depends, not on the action of the free sulphur and of the oxygen of the air, but upon the resolution of the sulphurous acid into sulphur, sulphuric acid, and trithionie acid:

A dilute solution of acid potassium sulphite enclosed in a sealed tube and first heated in the water-bath, then left to itself for four years, was found to have deposited sulphur and to contain sulphuric and trithionie acids, but no sulphurous acid or any other oxygen-acid of sulphur. Langlois, on the other hand, without questioning the results obtained by Saintpierre with dilute solutions, calls attention to the fact that in his own mode of preparation, which supposes the use of a saturated solution of potassium sulphite containing crystals in excess, the sulphur certainly takes part in the reaction, inasmuch as the liquid soon acquires a yellowish colour, which it does not lose till the acid sulphite is wholly converted into trithionate; sulphuric acid is not formed in any considerable quantity. Langlois regards it as most probable that the sulphur first converts the sulphite into thiosulphate, and that this salt is then converted into trithionate, according to the equation:

Seleniotrithionie Acid. $\text{H}_2\text{S}^3\text{SeO}^6$ (Rathke, *J. pr. Chem.* xcv. 1; *Jahresb.* 1865, p. 146).—The potassium salt of this acid is the less soluble of the two salts, formed, as already mentioned (p. 1075), by digesting selenium with neutral potassium sulphite. It is obtained in greatest quantity, but contaminated with 6 to 11 p. c. potassium sulphate, when the solution contains a certain quantity of acid potassium sulphite. It is also formed (like the trithionate) by digesting selenium with a solution of acid potassium sulphite at 50° to 60° , but only in small quantity, as it is easily decomposed by heat into selenium, sulphurous acid, and neutral potassium sulphite. It is moreover produced by evaporating a solution of seleniosulphate and acid sulphite of potassium (the thiosulphate formed at the same time may give rise to trithionate), and even crystallises in small quantity from neutral or alkaline solutions of selenium in sulphites, inasmuch as a certain quantity of acid sulphite is produced by the action of atmospheric carbonic acid. On the other hand, it is not formed by the action of free sulphurous acid on potassium seleniosulphate, or of selenious acid on the thiosulphate (in the latter case selenium and sulphur are separated, and potassium trithionate is formed on evaporation). The seleniotrithionate is obtained in greatest purity by mixing a solution of the thiosulphate containing excess of neutral sulphite with a concentrated solution of selenious acid. The liquid then becomes warm, and immediately yields a precipitate consisting of slender needles, which increases on cooling, and may be freed by washing with cold water from all but traces of foreign salts.

The seleniotrithionate obtained by the first process forms very thin prisms having a vitreous lustre and permanent in the air. It is anhydrous, forms a clear solution in water, but decomposes in solution in course of time, partly into potassium dithionate and free selenium (which explains the mode of formation of the dithionate mentioned in vol. v. p. 637), partly into selenium, potassium sulphate, and free sulphurous acid, the latter mode of decomposition taking place chiefly when heat is applied, or on evaporation in a vacuum over oil of vitriol. *Acids* do not precipitate the solution in the cold; but at the boiling heat they precipitate selenium and eliminate sulphurous acid. The pure seleniotrithionate does not yield a precipitate with *sulphurous acid* or *barium chloride*, whereby it is distinguished from the seleniosulphate. Heated with *ammoniacal silver solution* it is decomposed in the manner shown by the equation:

With *mercuric cyanide* under similar circumstances it yields mercuric selenide (Rathke).

SULPHUR SALTS. The following double sulphides have been obtained by fusing 1 pt. of a heavy metal with 6 pts. of potassium or sodium carbonate, and 6 pts. of sulphur, and lixiviating the fused mass with water (R. Schneider, *Pogg. Ann.* cxxvii. 460; cxxviii. 299, 604; *Zeitschr. f. Chem.* [2] v. 629; vi. 270).

Potassium-bismuth Sulphide, $K^2Bi^2S^4 = K^2S.Bi^2S^3$, crystallises in light steel-grey shining needles; the sodium salt, of similar composition, is obtained as a steel-grey mass made up of small crystals.

Potassio-cuproso-cupric Sulphide, $K^2Cu^2S^8 = K^2S.3(Cu^2)^2S.2CuS$, forms shining steel-blue laminae, which, when heated in a stream of hydrogen, give off one-sixth of their sulphur, the cupric sulphide being reduced to cuprous sulphide. **Sodio-cuproso-cupric Sulphide**, $Na^2Cu^2S^8 = Na^2S.(Cu^2)^2SCuS$, forms grey-blue needles, quickly decomposed by moist air, reacting with hydrogen like the potassium salt.

Potassium-iron Sulphide, $K^2Fe^2S^4$, forms purple-brown, flexible, shining needles, permanent in the air at ordinary temperatures, bearing a red heat in a close vessel without alteration, but oxidising to ferric oxide and potassium sulphate when heated in contact with the air. Dilute acids decompose it, with evolution of hydrogen sulphide and separation of sulphur. By ignition in hydrogen it is reduced to $K^2Fe^2S^4$ or $K^2S.2FeS$, which dissolves in hydrochloric acid without separation of sulphur. **Sodium-iron Sulphide** is a dark copper-coloured compound which when dried over sulphuric acid has the composition $Na^2Fe^2S^4 + 4H_2O$. On suspending it (or the potassium salt) in water and adding solution of silver nitrate, a precipitate of silver-iron sulphide, $Ag^2Fe^2S^4$, is formed, and ferrous nitrate passes into the solution, together with sodium-nitrate. Hence Schneider concludes that the two atoms of iron in the sodium (or potassium) salt have different equivalent values, and that the reaction just mentioned takes place as represented by the equation:

The silver salt, $Ag^2Fe^2S^4$, is black and crystalline, is attacked only by concentrated hydrochloric acid, and when ignited yields a sublimate of sulphur and a residue consisting of ferrous sulphide and metallic silver.

Potassio-ferroso-cuproso-cupric Sulphide, $K^2Fe^2(Cu^2)^2Cu^2S^8$, obtained by fusing 10.25 to 10.5 pts. copper with 3 pts. iron, 72 pts. potassium carbonate, and 72 pts. sulphur, and lixiviating, forms blue and red crystalline lamellae, which give off $\frac{1}{4}$ of their sulphur when ignited in hydrogen. A corresponding sodium salt is obtained in like manner.

Potassio-platinoso-sulphoplatinate, $K^2Pt^2Pt^2S^8$, is obtained by fusing 1 to 2 pts. platinum-sponge with 6 pts. potassium carbonate and 6 pts. sulphur, and lixiviating in large reddish crystals, having a sp. gr. of 6.44 (at 15°); permanent in the air at ordinary temperatures; decomposed by gaseous hydrogen chloride, with evolution of hydrogen sulphide; dissolved by aqueous hydrochloric acid, with formation of potassium chloride and without evolution of hydrogen sulphide, evidently producing the compound $H^2Pt^2Pt^2S^8$.

The hydrogen is however quickly expelled, and an atom of sulphur unite with a portion of the platinum sulphide, forming the compound $PtS.PtS^2$. This compound retains water till heated to 120°, it is steel-grey, crystalline, and has a sp. gr. of 5.52. Potassio-platinoso-sulphoplatinate heated in a stream of hydrogen gives off $\frac{3}{4}$ of its sulphur, leaving a mixture of $K^2S.PtS$ with metallic platinum. **Sodio-platinoso-sulphoplatinate**, $Na^2Pt^2Pt^2S^8$, is exactly analogous to the potassium salt.

Potassio-platinous Sulphostannate, $K^2Pt^2Sn^2S^8$, is obtained, by fusing 2 pts. platinum with 1 pt. stannic sulphide, 3 pts. potassium carbonate, and 3 pts. sulphur, and lixiviating with water, as a cochineal-red crystalline powder appearing under the microscope as a mass of six-sided tables. It gives off $\frac{3}{4}$ of its sulphur when heated in a stream of hydrogen, and when treated with dilute hydrochloric or acetic acid gives up all its potassium, and is converted into $H^2Pt^2Sn^2S^8$. This latter compound oxidises in the

air, the hydrogen going off as water, and the compound $Pt^2Pt^2Sn^2S^8$ being left.

Sodio-platinous sulphostannate is obtained by fusing 1 pt. platinum and $\frac{1}{2}$ pt. stannic sulphide with 3 pts. potassium carbonate, $\frac{1}{2}$ pt. sodium carbonate, and 3 pts. sulphur. By fusing 1 pt. platinum with 6 pts. sodium carbonate and 6 pts. sulphur, a mass traversed by red crystals is obtained, which cannot be washed with water contain

air without decomposing the crystals; these crystals consist of $Na^2Pt^2Sn^2S^8$. When subjected to prolonged washing with water, they leave a black-brown residue of platinum sulphide, PtS^2 . When washed with de-aerated water and treated with silver nitra

they yield a grey mass consisting of *argento-platinous sulphostannate*, $\text{Ag}^1\text{Pt}^2\text{Sn}^4\text{S}_8$, which is permanent in the air, is not decomposed by hydrochloric acid, but easily by nitric or nitromuriatic acid. The red sodium salt treated with thallious sulphate yields *thallio-platinous sulphostannate*, $\text{TI}^1\text{Pt}^2\text{Sn}^4\text{S}_8$. The sodium may also be replaced by various bivalent metals, as iron, manganese, cadmium, copper, lead, and mercury.

SYENITE. For analyses of this rock from various localities, see *Jahresb.* 1867, pp. 1020, 1028.

SYRINGA. Analyses of the ash of the leaves and flowers of the lilac (*Syringa vulgaris*) have been published by Wittstein (*Vierteljahrsschr. pr. Pharm.* xvi. 81): A. Leaves of the white-flowered variety: amount of ash after drying at $110^\circ = 4.389$ p. c.;—B. Leaves of the violet-flowered variety: ash at $110^\circ = 4.922$ p. c.;—C. White flowers (without calyx): ash at $110^\circ = 5.76$ p. c.;—D. Violet flowers (without calyx): ash at $110^\circ = 4.286$ p. c.:

T

TABERGITE. This mineral, from Taberg in Wermeland, Sweden, has been analysed by C. W. Fuchs (*Jahrb. Min.* 1867, p. 822), who finds it to contain:

SiO ₂	Al ₂ O ₃	FeO	MnO	MgO	CaO	K	Na	H ₂ O	F
32.95	13.08	13.72	0.07	26.83	0.95	0.33	1.25	11.34	0.97 = 101.49

leading to the formula $3[7(2\text{MgO} \cdot \text{SiO}_2) + 2(\text{Al}_2\text{O}_3 \cdot \text{SiO}_2) + 10\text{H}_2\text{O}] + 2(\text{K}; \text{Na})\text{F}$. The mineral, which is intermediate between chlorite and magnesia mica, is broadly laminar, perfectly cleavable, with nacreous to fatty lustre on the cleavage-faces. Predominant colour bluish-green, with silver-white to blackish spots. Hardness 2 to 2.5. Sp. gr. 2.813. Streak greenish-white.

TALTALITE. The mineral from Atacama so called by Domeyko (v. 657) is according to Ulex (*J. pr. Chem.* xvi. 37) a mixture of atacamite, malachite, red hæmatite, and limestone, traversed by crystals of turmalin, or according to Pisani (*Sill. Am. J.* [2] xliii. 37) a mixture of turmalin and cupric oxide.

TANITE. Laminar nickel-iron containing 13.2 p. c. nickel, occurring in meteorites (G. Rose, *Jahresb.* 1865, p. 945).

TANTALATES. On the classification and analysis of natural tantalates, see Blomstrand (*Jahresb.* 1865, p. 895; 1866, p. 944).

TANTALUM. Ta = 182.—The specific gravity of pure tantalic oxide or anhydride, Ta₂O₅, precipitated from tantalich chloride by ammoniacal water, and gently ignited, has been found by Deville a. Troost (*Compt. rend.* lxi. 294) to be 7.35.

The same chemists have redetermined the vapour-density of tantalich chloride, TaCl₅, and found it to be 12.8 at 360°, 13.0 at 440; calc. = 12.5. The pure chloride is pale yellow and crystallisable, melts at 211.3°, and boils at 241.6° under a pressure of 753 mm. Its vapour passed over ignited tantalich oxide does not form an oxychloride.

An alloy of tantalum and aluminium, TaAl₃, is obtained by fusing potassiotantalich fluoride with aluminium-foil in a crucible lined with charcoal, and treating the resulting regulus with hydrochloric acid to dissolve the excess of aluminium. The alloy then remains as a crystalline powder, having a sp. gr. of 7.02. It is but slightly attacked by strong boiling hydrochloric acid, not at all by nitric, nitromuriatic, or dilute sulphuric acid; but it is dissolved by hydrofluoric acid at ordinary temperatures, by strong sulphuric acid at the boiling heat, and by fused acid potassium sulphate (Marignac, *Bull. Soc. Chim.* [2] ix. 465).

Respecting Hermann's criticisms on Marignac's views of the constitution of the tantalum compounds, see *J. pr. Chem.* c. 385; *Bull. Soc. Chim.* [2] viii. 171;—for Marignac's reply: *J. pr. Chem.* ci. 459; *Zeitschr. f. Chem.* [2] iv. 91; *Jahresb.* 1867, p. 209.

TARCONINE. A product of the decomposition of narcotine tri-iodide (p. 865).

TARTARIC ACIDS. Paratartaric or racemic acid (or inactive tartaric acid) is formed by boiling glyoxal with dilute hydrocyanic acid and a small quantity of hydrochloric acid in a retort with upright condenser, adding hydrochloric acid from time to time. The liquid neutralised with milk of lime yields a calcium salt consisting essentially of calcium racemate (or inactive tartrate). The acid separated from it exhibits all the characters of ordinary racemic acid, but it is doubtful whether it is resolvable into dextro- and levo-tartaric acid. The mode of formation may be represented by the equation:

This mode of formation establishes the constitutional formula of the acids of the tartaric acid group. The acid obtained as above is quite distinct from Schöyen's glycotartaric acid (p. 650) (Strecker, *Zeitschr. f. Chem.* [2] iv. 216). Paratartaric acid is also formed, together with dibromosuccinic acid, by the action of bromine and water on phenaconic acid (Carius, p. 905). The paratartaric acid thus obtained agrees with natural racemic acid in crystalline form and in the form and composition of its calcium salt (v. 37).

When tartaric acid is subjected to *dry distillation*, an oily distillate of pyrotartaric acid is obtained between 170° and 210°, mixed with needles of pyrotartaric acid C⁷H⁴O⁸:

(Wislicenus a. Stadnicki, p. 981).

Tartaric acid subjected to *electrolysis* yields at the positive pole carbon dioxide and monoxide, together with oxygen; the solution contains acetic acid. A solution of 1 pts. neutral potassium tartrate in 32 pts. water yields chiefly carbon dioxide, with small quantities of carbon monoxide and oxygen, and deposits acid tartrate. A solution containing 4 mol. neutral potassium hydrate yields the same gases, together with a trace of ethane, and potassium acetate is formed in the liquid (Bourgoin, *Ann. C. Phys.* [4] xiv. 157; *Jahresb.* 1867, p. 385).

Tartaric acid is decomposed by heating with water to 180° in a sealed tube, the first product formed being probably pyrotartaric acid, but it undergoes further alteration (Morkownikoff a. Purgold, *Zeitschr. f. Chem.* [2] iii. 264).

When tartaric acid is heated with *hydrochloric acid* in sealed tubes, decomposition begins at 125°, and at 180° the tartaric acid is completely resolved into carbon dioxide, carbon monoxide, pyrotartaric acid, and a carbonaceous residue. Paratartaric acid similarly treated also yields pyrotartaric acid, the decomposition beginning at 130° and being completed at 160° (Geuther a. Riemann, *Zeitschr. f. Chem.* [2] v. 318).

When tartaric acid mixed with a solution of *leucoeballic chloride* (1 pt. of the s to 15 pts. water) is boiled with potash or soda, the yellow solution becomes first green then bluish-violet. This reaction may serve for the detection of tartaric acid

presence of some of the more ordinarily occurring organic acids. Malic, formic, benzoic, succinic, citric, acetic, and oxalic acids treated in like manner yield a precipitate of cobaltous hydrate, the acid being simply transferred to the potash. To apply this reaction, the tartaric acid, and any oxalic acid that may be present, are precipitated by calcium chloride and ammonia, the washed precipitate is boiled with a strong solution of sodium carbonate, and the filtrate, freed from carbonic acid by means of hydrochloric acid, is mixed with caustic soda and boiled with the luteocobaltic solution. A blue-violet coloration indicates the presence of tartaric acid. Tannic acid and paratartaric acid likewise yield a solution containing cobalt, but at the same time form a cream-coloured precipitate (C. D. Braun, *Zeitschr. anal. Chem.* 1868, p. 349).

On the distinction of tartaric from citric acid by means of permanganate solutions see CITRIC ACID (p. 472).

Martenson (*Zeitschr. f. Chem.* [2] v. 444) estimates tartaric acid as calcium tartrate, which he finds to be soluble in 2388 pts. of water, nearly insoluble in alcohol of 85 p. c., more soluble in aqueous sal-ammoniac or calcium chloride. The salt dried at 100° is dissolved in a small quantity of water in a perfectly glazed porcelain capsule, neutral solution of calcium chloride is added and a few drops of lime-water, taking care to avoid an excess, after which the liquid is stirred without touching the sides of the vessel, and left to itself for some hours. The liquid is then passed through a weighed filter, and after it has all run off, the precipitate is placed on the filter, together with a little alcohol, the liquid again allowed to run through, and the precipitate washed with alcohol, dried at 100°, and weighed as $C^4H^4CaO^8 + 4H^2O$.

Metallic Tartrates. Tartaric acid, as already observed (v. 675), is mostly bibasic, but it sometimes also exhibits the characters of a quadribasic acid, the alcoholic as well as the usually basic hydrogen-atoms being replaced by metals. The

quadribasic lead salt, $C^4H^2Pb^2O^8$, which Erdmann obtained by boiling the monoplumbic salt with aqueous ammonia, likewise separates as a crystalline powder, when neutral lead acetate is boiled for 8 to 12 hours with cream of tartar. It is quite insoluble in water, acetic acid, ammonium tartrate, and other ammoniacal salts, but dissolves easily in potash and in nitric acid. If the boiling be continued for 3 or 4 hours only, the *triplumbic salt*, $(C^4H^2O^8)^2Pb^3$, which is likewise insoluble, is obtained. A *quadri-*

basic zinc salt, $2C^4H^2Zn^2O^8 + H^2O$, is obtained by boiling tartaric acid with zinc and potash-solution and neutralising with nitric acid, as a powder insoluble in water, tartaric acid, and ammoniacal salts. When tartaric acid is boiled with zinc alone, the ordinary bibasic salt, $C^4H^2Zn^2O^8$, separates out. The *potassium-bismuth salt*, $C^4H^2Bi^2KO^8$, prepared by Schwarzenberg (v. 686), is decomposed by water, with formation of a white, insoluble basic salt, which, when dried at 200°, has the composition $C^4H^2Bi^2KO^8.C^4H^2Bi^2(O^8)O^8$. *Potassio-uronic tartrate*, $C^4H^2K(VO^8)O^8$ (at 200°), is obtained as an amorphous powder by boiling recently precipitated uranic hydrate with cream of tartar and evaporating the filtrate (Frisch, *J. pr. Chem.* xevii. 278; *Jahresb.* 1866, p. 401).

According to Fleury (*Compt. rend.* lxxvii. 957) the double tartrates analogous to tartar-emetic are always produced when a salt of a trioxide or sesquioxide and a salt of a monoxide are brought in contact with tartaric acid in acid or in alkaline solution. Thus when bismuth nitrate is dissolved by agitation in a solution of tartaric acid supersaturated with soda, a liquid is obtained, which, when largely diluted with water, is precipitated by salts of barium, calcium, magnesium, &c. The compounds thus formed are very slightly soluble in water, soluble in acids and in caustic soda. Analogous double salts are formed by malic and citric acid.

The optical and crystallographic characters of the acid tartrates of ammonium, thallium, rubidium, and cesium have been examined by v. Lang (*Zeitschr. f. Chem.* [2] iii. 450). The last three form crystals belonging to the rhombic system, isomorphous with the acid tartrates of ammonium and potassium. The proportions of the axes are as follows:

	Brachy- diagonal	Macrodia- gonal	Principal axis.
For $C^4H^2TlO^8$:	0.6911	1	0.7186
" $C^4H^2RbO^8$:	0.6873	1	0.7010
" $C^4H^2CsO^8$:	nearly the same.		
" $C^4H^2KO^8$ (according to Schabus) :	0.7115	1	0.7372
" $C^4H^2(NH^4)O^8$ (acc. to De la Provostaye) :	0.6983	1	0.7086

Potassium Tartrates.—According to E. Kiesel (*Zeitschr. anal. Chem.* 1869, 409) 1 pt. of acid potassium tartrate dissolves in 230.1 pts. water at 10°, in 203.1 pts. at 15°, and in 152.1 pts. at 22°; 1 pt. dissolves at 12° in 318.5 pts. spirit of 6 p. c. in

360 pts. spirit of 8 p. c., in 378 pts. of 9 p. c., in 402 pts. of 10 p. c., and in 441 pts. of 12 p. c. After addition of 0.2 p. c. glacial acetic acid, spirit of 10 p. c. dissolves only 2.424 grm. of cream of tartar in a litre, the spirit alone dissolving 2.487 grm. After addition of 0.1 p. c. tartaric acid, a litre of the same spirit dissolves only 1.920 grm.

Bussy a. Buignet (*Compt. rend.* lx. 976) have examined the reaction between acid potassium tartrate and gypsum, with reference to the addition of gypsum to wines, practised in the south of France. When a solution of 2 grms. cream of tartar in 500 c.c. water containing 0.1 p. c. alcohol is digested with 0.915 grm. gypsum (equivalent proportions of the two salts), a reaction takes place represented by the equation:

the calcium appearing in the product as neutral tartrate, while the potassium remains in solution, half as acid tartrate, half as acid sulphate. Any further addition of calcium sulphate remains undecomposed, partly in the liquid, partly in the precipitate. Analogous transformations take place when gypsum is added to wine. Chancel, on the other hand (*Compt. rend.* lx. 408), supposes that neutral potassium sulphate and free tartaric acid are formed, together with the neutral calcium tartrate. He also observes that the action of the gypsum goes farther, if, instead of being added to the wine, it is added, according to general custom, to the must together with the lees. The quantities of acid potassium tartrate dissolved in 1000 pts. of pure water (I.), and of water containing 10.5 p. c. alcohol (II.), are, according to Chancel, as follows:

	0°	5°	10°	15°	20°	25°	30°	35°	40°
I.	2.44	3.00	3.70	4.53	5.53	6.70	8.05	9.60	11.30
II.	1.41	1.75	2.12	2.53	3.05	3.72	4.60	5.70	7.10

The solubility diminishes as the proportion of alcohol in the water increases; the presence of glucose, on the other hand, has no perceptible influence on it. The young and unplastered wine prepared in the south of France contains therefore from 2.5 to 3.5 grm. of cream of tartar in the litre; and as the corresponding quantity of grapes contains from 9 to 10 grm., it follows that the greater part of the acid tartrate remains in the lees. By addition of gypsum to the must, this undissolved tartar is decomposed. A saturated solution of acid potassium tartrate in water contains, after three days' digestion at 35° with excess of gypsum, 0.97 grm. tartaric acid in the litre, but when an undissolved excess of the acid tartrate is present, it contains 2.11 grm. tartaric acid in the litre. In wine thus plastered Chancel found 2.17 grm. potash in the litre; in wine fermented without gypsum, only 0.585 grm. The plastering of the must brings therefore half the tartaric acid in the must and the greater part of the potash into the wine, and, besides its clarifying action, has an important influence on the colour and durability of the wine by increasing the amount of acid in it. For Bussy a. Buignet's criticisms on Chancel's results, see *J. Pharm.* [4] i. 351; ii. 5.

Crude tartar containing a considerable quantity of yeast is apt to undergo fermentation, which diminishes the proportion of tartaric acid. A tartar containing originally 44.8 p. c. of the pure acid tartrate was found by J. Haerlin (*Dingl. pol. J.* clxxxv. 218) to contain, after 8 days' fermentation 30 p. c., after 14 days 24 p. c., and after 4 weeks only 14.8 p. c. of pure cream of tartar. Many crude tartars contain, as products of decomposition, easily soluble potassium salts difficult to crystallise.

Calcium tartrate, $\text{C}^4\text{H}^3\text{CaO}^6 \cdot 4\text{H}^2\text{O}$, requires for solution 6265 pts. of water at 15°, and 352 pts. at the boiling heat (F. Mohr, *Vierteljahrs. pr. Pharm.* xiv. 428).

TARTRONIC ACID. $\text{C}^3\text{H}^3\text{O}^3$.—This acid heated with saturated aqueous hydriodic acid yields ethane and carbon dioxide, being first converted into malonic acid, $\text{C}^3\text{H}^3\text{O}^4$, which is then resolved into acetic acid and carbon dioxide, $\text{C}^2\text{H}^3\text{O}^1 + \text{C}^2\text{H}^3\text{O}^2 + \text{CO}^2$ (Berthelot).

TEA. Tea-leaves contain, according to Hlasiwetz a. Malin (*J. pr. Chem.* ci. 109), besides the constituents hitherto observed (theine, quercitannic acid, boheic acid), also gallic acid, oxalic acid, and quercetin, the latter most probably existing originally, for the greater part at least, as quercitrin. The precipitate formed in an infusion of tea by neutral lead acetate contains chiefly quercitannic, gallic, and oxalic acids; the precipitate thrown down from the filtrate by basic lead acetate contains, besides the acids just mentioned, a yellow lead-compound, which, by decomposition with hydrogen sulphide and boiling of the filtrate with sulphuric acid, yields quercetin, $\text{C}^{27}\text{H}^{10}\text{O}^{12}$, together with sugar. The presence of quercetin (or of quercitrin) in tea explains the fact that when the substances precipitable by basic lead acetate are oxidised with potassium hydrate, protocatechuic acid and phloroglucin are produced.

TELÆSCIN. $C^{18}H^{30}O^7$.—A product of the decomposition of æscinic acid by acids. (See HORSE-CHESTNUT, iii. 172.)

TELLURIUM. Tellurium ores (gold and silver tellurides) occur in masses on the Calaveras range between the river Stanislas and the Albany mountains in California (Mathewson, *Jahrb. Min.* 1866, p. 93). On the preparation of tellurium see H. Schwartz (*Dingl. pol. J.* clxxvi. 29; *Jahresb.* 1867, p. 257).

TENORITE. On the crystalline form and optical characters of this mineral, see Maskelyne (*Rep.* 35, *Br. Assoc. Notices and Abstracts*, p. 33; *Jahresb.* 1867, p. 979).

TEREPHTHALIC ACID. See PHTHALIC ACID (p. 942).

TERPILENE. See TURPENTINE OIL.

TESCHENITE. A variety of diorite occurring at Teschen and other localities in Hungary (Tschermak, *Wien. Akad. Ber.* liii. [1] 26; *Jahresb.* 1866, p. 976;—Fellener, *Jahrb. Min.* 1868, p. 207; *Jahresb.* 1867, p. 1028).

THALLIUM. Nordenskiöld (*Ann. Ch. Pharm.* cxliv. 127) has found from 16.2 to 18.5 p. c. thallium in a selenide of copper and silver from Skrikerum in Sweden, which he designates as *Crookesite*.

For the preparation of thallium from the flue-dust of pyrites burners, Wöhler (*ibid.* cxlii. 263) recommends the following process. The dust is repeatedly boiled with water acidulated with sulphuric acid; the filtered extract, not previously concentrated (otherwise arsenic would be precipitated at the same time), is mixed with hydrochloric acid, which throws down thallium chloride, and this compound, after washing with water, is converted into neutral sulphate, from the solution of which, to avoid contamination with other metals, the thallium is precipitated by electrolysis. For this purpose, a wide glass tube, tied round with bladder at the bottom, is suspended in the liquid, and filled up to the height of the thallium solution with acidulated water, and within it is fixed a plate of zinc, connected at its upper end with a platinum or copper wire immersed in the thallium solution. The thallium, which in the course of a few days is completely precipitated on the wire, is washed, with as little contact of air as possible, then pressed between paper, dried, and fused to a regulus with potassium cyanide. Carstanjen (*J. pr. Chem.* cii. 65) considers it better to knead the precipitated thallium to a solid mass under water, then hammer it into dense cubes, fuse these, previously well dried, in a porcelain crucible without the addition of any flux, and cast the metal into ingots. The small quantity of thallious oxide formed in the fusion serves to remove any metallic impurities that may be present.

Gunning (*Archives néerlandaises*, iii. 86) prepares thallium from a flue-dust consisting chiefly of arsenious and arsenic acid, together with oxides of lead and iron, by means of phosphoric acid. The dust is heated with a mixture of bone-ash, sulphuric acid, and water; the mass is strained; the residue again treated in the same manner, and the united extracts precipitated by hydrochloric acid. The filtrate containing thallium, partly as thallious chloride, partly in the form of thallic salts, is mixed with sodium sulphite; partially neutralised with sodium carbonate, and the thallium is precipitated as iodide. To prepare pure thallium salts from the crude chloride (which contains arsenic), it is best, according to Gunning, first to convert it into thallic oxide, by suspending it in a solution of sodium carbonate and passing chlorine into the liquid, taking care to keep it alkaline by adding fresh lumps of sodium carbonate if necessary. The conversion is rapid and complete. The trioxide is carefully washed, suspended in water, and reduced to thallious sulphate by passing sulphurous acid gas into the liquid. The resulting solution slowly evaporated in the air or over sulphuric acid yields pure crystals.

Oxidation.—Thallium is oxidised at ordinary temperatures by solution of potassium permanganate (Crookes, *Bull. Soc. Chim.* [2] vii. 394). When made to form the positive pole of a battery of two Bunsen's elements in water acidulated with sulphuric acid, it is converted into the black trioxide (Wöhler, *Zeitschr. f. Chem.* [2] v. 385). Paper impregnated with a thallious salt is turned brown by ozone, and was recommended by Schönbein as a delicate test for ozone. According to Laing (*ibid.* v. 416) thallium-paper may be turned brown without the action of ozone, and cannot thereby be regarded as a sure test for the latter, unless its indications are corroborated by the bluing of guaiacum-paper. With this limitation, it is a more delicate test than iodised starch-paper, and will detect ozone even in an atmosphere containing a considerable quantity of nitrous acid; it cannot however be trusted as a quantitative indicator.

Thallium Alloys. Several of these alloys have been studied by Carstanjen (*J. pr. Chem.* cii. 65; *Zeitschr. f. Chem.* [2] iv. 69), with the following results:

Alloy of :	Proportions	Solidifying Point	Colour ; Hardness
Thallium and Zinc	Equivalent proportions	above 360°	Soft like thallium. Cast bars crackle when bent
Thallium and Cadmium	"	184°	Silver-white ; fine-grained ; crystalline ; harder than the zinc alloy
Thallium and Bismuth	"	170°	Reddish-grey ; crystalline, but soft
Thallium, Cadmium, and Bismuth	6 pts. Tl, 5 pts. Bi, 1 pt. Cd	134°	Hard, brittle ; recent fracture bright grey ; finely granulo-crystalline
Thallium and Lead	Equivalent proportions	above 250°	Soft, non-crystalline ; lead-coloured
Thallium, Lead, Bismuth	1 pt. Tl, 6 pts. Bi, 6 pts. Pb	130°	Somewhat crystalline ; hard, shining
Thallium and Tin	Equivalent proportions	—	Difficult to fuse, soft, slightly ductile ; does not tarnish
Thallium, Tin, Bismuth	1 pt. Tl, 2 pts. Bi, 1 pt. Sn	115°	Hard, fine-grained, light grey to white
Thallium and Copper	Equivalent proportions	Fusible only under borax at a white heat	Brass-yellow ; may be cut with a knife, tarnishing on the cut surface
Thallium and Aluminium	Equivalent proportions	Do.	Tough, but softer than thallium ; oxidises without burning when heated in the air
Thallium and Magnesium	Equal parts		Easily alterable ; burns with magnesium flame when heated in the air

All these alloys, except that of tin, tarnish in the air ; they are more or less attacked by dilute sulphuric acid, with evolution of hydrogen.

An alloy of equal parts of thallium and *arsenic* is blackish-grey and crystalline, but soft enough to be cut with a knife. The silver-white cut surfaces acquire a blue and yellow tarnish on exposure to the air. With dilute sulphuric acid, the alloy gives off large quantities of trihydric arsenide, and deposits a brown powder. The alloy of thallium and *antimony* in equal parts is very hard, brittle, crystalline, and has a grey fracture ; with dilute sulphuric acid, it gives off trihydric antimonide. The alloys of thallium with *potassium* and *sodium* in equivalent proportions are soft and crystalline, deliquesce in the air, and decompose water with violence. The sodium alloy may be kept under petroleum ; the potassium alloy is altered thereby, acquiring a brown colour. *Thallium amalgam* containing equivalent proportions of thallium and mercury

has the consistence of butter and is alterable in the air (Carstanjen). According to Nicklès (*J. Pharm.* [4] iv. 27) thallium is easily wetted and penetrated by mercury. According to J. Regnaud (*Compt. rend.* lxiv. 611) the amalgamation of thallium is attended with evolution of heat, and therefore, in accordance with a law previously established by Regnaud, the amalgam is electronegative towards the pure metal.

Chloride. A compound of thallous chloride with ferric chloride, $6\text{TiCl} \cdot \text{Fe}^2\text{Cl}_6$, is formed when recently precipitated thallous chloride is added to a concentrated solution of ferric chloride mixed with a large excess of fuming hydrochloric acid, or when thallous chloride is heated to fusion in vapour of ferric chloride. The bright cinnabar-red compound is soluble in hot concentrated hydrochloric acid, and crystallises from the cooling solution in small translucent prisms permanent in the air. It is immediately decomposed by water into thallous and ferric chlorides, and can therefore be obtained in the dry state only by washing with strong hydrochloric acid, leaving it over slaked lime, and finally warming it in a current of dry carbon dioxide. The same compound is separated as a heavy red precipitate on adding a large quantity of hydrochloric acid to the liquid obtained by lixiviating the flue-dust of thalliferous iron pyrites (Wöhler, *Ann. Ch. Pharm.* cxliv. 250).

Oxides. The trioxide, or thallic oxide, is formed by the action of hydrogen dioxide on metallic thallium. The precipitate dried over sulphuric acid has the composition of the monohydrate $\text{Ti}^3\text{O}_5 \cdot \text{H}_2\text{O}$ or $\text{Ti}^3\text{H}_2\text{O}_6$, and becomes anhydrous when dried at 100° (Birnbau, *Ann. Ch. Pharm.* cxviii. 133).

Thallic oxide detonates when triturated with flowers of sulphur, and slowly takes fire when triturated with 8 pts. of gold sulphide (Böttger, *Zeitschr. f. Chem.* [2] iv. 57).

When a rapid stream of chlorine is passed through potash-ley in which thallic oxide is suspended, the liquid acquires a deep violet-red colour, in consequence of the formation of potassium thalliate. The solution of this salt may be evaporated, diluted, and filtered through paper without decomposition; but it is reduced by oxacids to a thallous salt with rapid evolution of oxygen, by hydrochloric acid with evolution of chlorine and precipitation of thallous chloride (Carstanjen).

Oxygen-salts.—Several of these salts have been further examined by Carstanjen (*J. pr. Chem.* cii. 65, 129; *Jahresb.* 1867, p. 275); by Flemming (*Bull. Soc. Chim.* [2] x. 35; *Jahresb.* 1868, p. 350); and by Lang a. Descloizeaux (*Ann. Ch. Phys.* [4] xvii. 310; *Jahresb.* 1868, p. 352). See the several Acids.

Phosphide (?). Thallium and phosphorus do not unite when fused together; neither is thallium phosphide formed by igniting the phosphate with charcoal or hydrogen (Carstanjen). Solutions of thallous salts do not act upon phosphorus; in the solution of thallous hydrate, phosphorus becomes covered with a black deposit, becoming metallically lustrous when heated, dissolving slowly in dilute hydrochloric acid (thallium?). When phosphorus is heated with a solution of thallous hydrate in sealed tubes, a small quantity of hydrogen phosphide is evolved, and a black mass separates, whilst small whitish crystals are deposited in the tube, and phosphorous acid remains in solution (Flemming, *Jahresb.* 1868, p. 250).

Selenide. Thallium and selenium heated together in equivalent proportions unite readily without incandescence. The resulting compound, Ti^2Se , is black, easily fusible; in the solid state it is scoriaceous and vesicular, hard, brittle, and changes colour on exposure to the air. It is not attacked by water, and dilute sulphuric acid attacks it only when heated, dissolving it slowly with evolution of hydrogen selenide. When the quantity of selenide used is between 1 and 3 eq. the product crystallises on cooling in radiating prisms which are permanent in the air, resist the action of dilute sulphuric acid, and are attacked by the concentrated acid only when heated, sulphurous oxide being then evolved. A definite triselenide does not appear to be producible in the dry way (Carstanjen).

Sulphides. Thallium forms a monosulphide, a trisulphide, and intermediate sulphides. The *monosulphide*, Ti^2S , is formed by precipitation of neutral thallous salts with hydrogen sulphide or ammonium sulphide (v. 756), also by fusing 204 pts. thallium with 16 pts. sulphur at the heat of a blast furnace. It is then obtained as a black, shining, brittle mass having a crystalline structure. The *trisulphide*, Ti^4S_3 , obtained by fusing 2 at. thallium with more than 3 at. sulphur, and volatilising the excess of sulphur without contact of air, is black, easily fusible, soft, and ropy at summer temperature; brittle, with vitreous fracture, below 12° . It is attacked by dilute sulphuric acid when heated, and dissolved without separation of sulphur; neither does it give up sulphur to carbon bisulphide. Fused with the monosulphide, it yields an intermediate sulphide crystallising in grey-black prisms. Intermediate crystallisable thallium sulphides of variable composition are likewise produced by precipitating the so-called sesquichloride (v. 747) with ammonium sulphide, or by fusing 2 at. thallium with more than one and less than three atoms of sulphur; two such sulphides

exhibited the composition TiS , TiS^2 and 5TiS , 3TiS^2 . They do not yield any sulphur to carbon bisulphide, but give up part of their sulphur (as also does the trisulphide) when heated in an open glass tube. All the sulphides of thallium are decomposed by ignition in a stream of hydrogen (Carstanjen).

Thallium sulpharsenate is formed as a reddish-yellow precipitate when hydrogen sulphide is passed into a neutral or acid solution of a thallious salt mixed with arsenious acid, or when an ammoniacal solution of arsenious sulphide is mixed with the ammoniacal solution of a thallious salt. When precipitated from acid solutions containing excess of thallium, it has the composition TiS , As^2S^3 . A similar precipitate is formed when hydrogen sulphide is passed into crude thallium chloride prepared from arsenical flue-dust, or into the crude aqueous extract of such flue-dust. When a solution containing arsenious acid and thallious sulphate in the proportion to form the sulpharsenite is treated with hydrogen sulphide, the whole of the arsenic is precipitated, but not all the thallium, a portion of that metal remaining in solution even when the arsenic is in considerable excess. On adding more arsenious acid a fresh precipitate containing thallium is formed, and by continuing this treatment the whole of the thallium may ultimately be precipitated. All the precipitates formed as above have the same colour (Gunning, *Archives néerlandaises*, iii. 86; *Jahresb.* 1868, p. 249).

THEOBROMINE. A solution of this base in strong hydrochloric acid mixed with potassium iodide and left to itself, deposits large nearly black prisms consisting of the periodide $\text{C}^2\text{H}^4\text{N}^4\text{O}^2\text{I}^4$; this compound is decomposed even by heating with alcohol (Jørgensen, *Zeitschr. f. Chem.* [2] v. 675).

THERMO-CHEMISTRY. Further determinations of the heat of neutralisation of acids and bases have lately been published by Thomsen (*Pogg. Ann.* cxliii. 354-396 and 497-534; *Deut. chem. Ges. Ber.* iv. 586).

The following tables give the numbers of thermal units (gramme-degrees) evolved when one molecule of hydrogen sulphate, H^2SO^4 , or an equivalent quantity of another acid, diluted with 400 molecules of water, is neutralised by an equivalent quantity of base in the same state of dilution:

TABLE I.

THEVETIA. The seeds of *Thevetia nerifolia*, an ornamental plant cultivated in India, and indigenous in the Mauritius or the West Indies, yields an oil of agreeable taste, liquid at ordinary temperatures, and containing 63 p. c. olein and 37 p. c. palmitin (besides stearin) (Oudemans, *Jahresb.* 1866, p. 697).

THIACETIC ACID. See ACETIC ACID (p. 20).

THIOBENZAMIDE. See BENZAMIDE (p. 238).

THIOBENZOIC ACID. See BENZOIC ACID (p. 324).

THIOCHRONIC ACID. See QUINONES (p 990).

THIONESSAL. $C^{22}H^{10}S$.—This compound, discovered by Laurent, who assigned to it the formula $C^{22}H^{10}S$ (v. 779), has been further examined by Fleischer (*Ann. Ch. Pharm.* cxliv. 192), and by Dorn (*Zeitschr. f. Chem.* [2] v. 597). It is produced by dry distillation of thiobenzene, benzyl sulphide, benzyl disulphide, or sulphobenzide. When benzyl sulphide, $(C^6H^5)^2S$, is distilled, toluene and benzyl sulphhydrate pass over at first, then toluylene (stilbene), and lastly, at a very high temperature, toluyl sulphide and thionessal. The distillate may be freed from a yellow oil and toluyl sulphide, by treatment with a large quantity of ether, and the thionessal, which remains undissolved, crystallised from boiling alcohol. Thionessal crystallises in small white needles melting at 180° ; it is not altered either by melting potassium hydrate or by heating with sodium (Fleischer).

Tribromothionessal, $C^{22}H^7Br^3S$, is formed on adding bromine to thionessal suspended in water, as a yellowish granular powder, which, after washing with hot alcohol and ether, crystallises from petroleum of high boiling point in hard microscopic needles. It melts at 265° – 270° , is not attacked by alcoholic potash or by benzene and sodium at the boiling heat, but is decomposed by fusion with sodium. By further treatment with bromine it is converted into *tetrabromothionessal*, $C^{22}H^4Br^4S$, which is quite insoluble in alcohol, ether, and petroleum (Fleischer).

Thionessal heated to 130° – 140° with 2 mol. phosphorus pentachloride, is decomposed according to the equation:

forming an oily compound which solidifies with water, dissolves sparingly in alcohol, easily in hot ether or benzol, and separates therefrom in needles melting at 130° – 132° . This body, C^6H^5Cl , or a multiple thereof, is not altered by heating with water or alcoholic ammonia to 180° , or by heating with benzol and sodium (Fleischer). According to Dorn, on the other hand, thionessal is not desulphurised by phosphorus pentachloride. When the two are heated together in an open vessel, *dichlorothionessal*, $C^{22}H^{12}Cl^2S$, is formed in white crystals melting at 219° ; in sealed tubes, 4 at. hydrogen are replaced by chlorine, but the sulphur remains in the molecule. Dorn also finds that thionessal may be passed over finely divided iron at a low red heat without alteration; over copper at the same temperature the greater portion passes unaltered, only a small quantity of a compound melting at 60° being formed, probably toluene. Thionessal treated with hydrochloric acid and potassium chlorate is converted into oxylepidene, and dichlorothionessal in like manner into dichloroxylepidene (Dorn).

Fuming nitric acid acts strongly on thionessal, producing, in the first instance, light yellow, amorphous nitrothionessal, $C^{22}H^{10}(NO^2)^2S$, then a nitro-compound free from sulphur, $C^{22}H^{10}(NO^2)^3O$, and lastly paranitrobenzoic acid together with sulphuric acid. *Tribromothionessal* treated with nitric acid yields a yellow powder, $C^{22}H^7Br^3(NO^2)^3O$, slightly soluble in hot alcohol, and an acid, $C^{22}H^{17}(Br^3)(NO^2)^3O$, which dissolves easily in alcohol and ether, melts at 180° , and forms a barium salt, $C^{22}H^{15}Ba^2Br^3(NO^2)^3O + 8H^2O$, crystallising in yellowish nodules. Thionessal dissolves in fuming sulphuric acid at ordinary temperatures, and in ordinary sulphuric acid when heated, forming a deliquescent acid, $C^6H^5SO^4$, which crystallises from alcohol in laminae or tufts of needles, and yields a barium salt, $(C^6H^5SO^4)^2Ba + 4H^2O$, crystallising in hard crusts, and a zinc salt, $(C^6H^5SO^4)^2Zn$, crystallising in deliquescent needles or laminae. When vapour of thionessal is passed over red-hot soda-lime, toluyl sulphide collects in the receiver in the form of a yellow powder (Fleischer).

Thionessal and toluyl sulphide are the sulphur-compounds analogous to lepidene and oxylepidene (p. 780).

Dorn represents these four compounds by the following constitutional formulæ:

THIOSINAMINE. $C^4H^4N^2S = N^2(CS)^{(C^2H^2)}H^2$. *Allylsulphocarbamide* (v. 781).—Several new derivatives of this compound have been obtained by Maly (*Zeitschr. f. Chem.* [2] v. 258).

Thiosinamine Iodide, $C^4H^4N^2SI^2$, is formed, like the bromide (v. 782), by direct combination of iodine with thiosinamine in alcoholic solution. It is soluble in water and in alcohol, and separates from the latter in brittle, nearly colourless groups of crystals; begins to melt and decompose at 90° ; and at a higher temperature gives off violet vapours, afterwards products having the odour of allyl compounds, and at a higher temperature volatilises completely. Strong sulphuric acid colours the solution violet and eliminates hydriodic acid; strong nitric acid separates the iodine as a black powder. Silver nitrate removes all the iodine, but recently precipitated silver chloride takes away only 1 at. iodine, replacing it by chlorine, and forming *thiosinamine iodochloride*, $C^4H^4N^2SiCl$, which separates from alcohol in colourless crystals, easily soluble in water and alcohol, melting to a yellow liquid and decomposing at a higher temperature. By treating the aqueous solution of the di-iodide with silver cyanide, and evaporating the filtered liquid, a compound of *thiosinamine iodoxyanide* with *silver cyanide* is obtained, as a heavy whitish-yellow powder, which when once separated from the liquid is insoluble in water, alcohol, ether, and ammonia. It is decomposed by strong sulphuric acid, and when heated, swells up in snake-like forms, like the sulphocyanates of mercury.

Thiosinamine Ethyliodide, $C^4H^4N^2S.C^2H^5I$, is obtained by dissolving equivalent quantities of thiosinamine and ethyl iodide, and leaving the solution to evaporate till it becomes syrupy. It then separates in large, colourless, transparent, well-defined crystals, which dissolve in all proportions of water, very easily in alcohol and ether, and decompose at 72° . Silver solution removes all the iodine. The corresponding *amyl compound*, $C^4H^4N^2S.C^5H^{11}I$, forms large, colourless, deliquescent crystals. Benzoyl chloride appears to form a similar compound with thiosinamine.

Thiosinamine Dicyanide, $C^4H^4N^2S.(CN)^2$, prepared by passing cyanogen gas into an alcoholic solution of thiosinamine, and purified by repeated crystallisation from hot alcohol, forms a loose network of shining, golden-yellow, crystalline laminae, moderately soluble in boiling alcohol, very slightly in benzol and ether, insoluble in water. The yellow alcoholic solution does not yield silver cyanide when boiled with silver oxide. The compound dissolves easily in potash, giving off ammonia when heated, and forming a faintly yellowish solution, with light green fluorescence.

Oxalyl-thiosinamine, $C^4H^4N^2SO^2 = N^2(CS)^{(C^2O^2)}(C^2H^2)H^2$, is formed by dissolving thiosinamine dicyanide in warm dilute sulphuric acid, and separates on cooling in large groups of lemon-yellow needles, the mother-liquor retaining a portion of it, together with ammonium-sulphate:

Oxalyl-thiosinamine is moderately soluble in cold, easily in hot water, very soluble in alcohol and ether. It melts at 80° – 90° , and burns with flame on platinum foil. The aqueous solution has a distinct acid reaction, is not clouded by barium chloride, but gives with silver nitrate, lead acetate, and baryta-water, precipitates which quickly decompose. The solution is decolorised by strong nitric acid, and then gives the reaction of that acid. With zinc and dilute sulphuric acid it becomes decolorised and gives off hydrogen sulphide. Strong sulphuric acid dissolves it with orange-red colour; potash does not perceptibly alter it. By baryta-water it is resolved into thiosinamine and oxalic acid: $C^4H^4N^2SO^2 + BaH^2O^2 = BaC^2O^4 + C^4H^4N^2S$. With silver nitrate in aqueous solution it yields silver sulphide and a silver compound of oxalyl-allyl urea, $N^2(CO)(C^2O^2)(C^2H^2)H^2$, which crystallises in groups of white silky needles. If the oxalyl-thiosinamine be boiled with excess of silver nitrate, silver oxalate and allyl urea are produced.

Phenyl-thiosinamine, $C^4H^4(C^6H^5)N^2S$ (v. 783), unites with iodine like thiosinamine, but the compound does not crystallise. Bromine, on the other hand, decomposes phenyl-thiosinamine. *Phenyl-thiosinamine dicyanide*, $C^4H^4N^2S.(CN)^2$, is formed by passing cyanogen gas into an alcoholic solution of phenyl-thiosinamine, and may be obtained, by precipitation with water and recrystallisation from alcohol, as a mass of crystals grouped in stellate forms; but it is not easily purified from adhering phenyl-thiosinamine. When its alcoholic solution is heated with dilute sulphuric acid, the entire liquid solidifies to a mass of long, very slender needles of oxalyl-phenyl-thiosinamine:

This compound is insoluble in water, slightly soluble in cold alcohol, very easily in hot alcohol and benzol, soluble also in ether and in amyl alcohol. It is decolorised by hot nitric acid, but without formation of sulphuric acid; dissolves readily in strong sulphuric acid, and is precipitated by water, apparently unaltered. It melts at 161° to a clear yellow liquid, and solidifies on cooling to a radio-crystalline mass. Treated in hot alcoholic solution with baryta-water, it is resolved into oxalic acid and phenyl-thiosinamine. The warm alcoholic solution forms with silver nitrate a precipitate of silver sulphide and a solution of *oxalyl-phenyl-allyl-carbamide*, $N^2(CO)(C^2O^2)(C^3H^3)(C^6H^5)$, the reaction consisting in a simple interchange of sulphur and oxygen. Oxalyl-phenyl-allyl-carbamide is insoluble, but dissolves easily in strong alcohol, benzol, carbon bisulphide, and warm amyl alcohol; melts at 108° ; is not precipitated by metallic salts; dissolves in strong sulphuric and in strong nitric acid, and is reprecipitated by water. By baryta-water it is resolved into oxalic acid and phenyl-allyl-carbamide, $N^2(CO)(C^3H^3)(C^6H^5)H^2$, which crystallises in shining white needles melting at 96° – 97° .

Tolyl-thiosinamine, $C^3H^3N^2S = C^3H^3(C^6H^5)N^2S$, first obtained by Jaillard (v. 874), is more easily prepared by mixing an alcoholic solution of toluidine with oil of mustard. The liquid solidifies after a while to a crystalline pulp containing tolyl-thiosinamine and another compound, which may be easily separated by hot alcohol, in which the former dissolves very easily, the latter with difficulty. Tolyl-thiosinamine separates from the alcoholic solution, on cooling, in soft white crystalline masses, consisting when dried of unctuous laminae. It melts at 97° (at 112° according to Jaillard).

Oxalyl-tolyl-thiosinamine, $C^3H^3N^2SO^2 = N^2(CS)^2(C^2O^2)(C^3H^3)(C^6H^5)$, is produced by saturating an alcoholic solution of tolyl-thiosinamine with cyanogen gas, and heating it after a while with dilute sulphuric acid. The liquid on cooling solidifies to a mass of yellow needles, which when washed with alcohol and water, and recrystallised from hot alcohol, yields oxalyl-tolyl-thiosinamine in long golden-yellow, rather narrow, and very flat needles, having a metallic lustre. It dissolves easily in hot, slightly in cold alcohol, forming a neutral solution; is insoluble in water, but soluble in ether, benzol, methyl alcohol, amyl alcohol, and carbon bisulphide. It melts at 157° to a deep yellow liquid, which soon solidifies to a crystalline mass; may be sublimed completely and without decomposition in a glass tube. Strong sulphuric acid dissolves it to a yellow liquid, from which it appears to be precipitated by water in its original state. Silver nitrate forms in the alcoholic solution a precipitate of silver sulphide; auric chloride forms a precipitate having the colour of ferric oxide; platinum chloride forms no precipitate. Hot strong nitric acid dissolves oxalyl-tolyl-thiosinamine without alteration. Baryta-water decomposes it into oxalic acid and tolyl-thiosinamine (Maly).

THOMSONITE. A mineral from Iceland having the optical properties of thomsonite (faroelite) was found by F. v. Kobell (*J. pr. Chem.* xcviii. 134; *Jahresh.* 1866, p. 940) to contain 41.00 p. c. SiO_2 , 31.66 Al_2O_3 , 4.50 Na_2O , and 12.11 water, leading to the formula $2Na_2O \cdot 3SiO_2 + 3(2CaO \cdot SiO_2) + 5(2Al_2O_3 \cdot 3SiO_2) + 10H_2O$.

THYMOL. C^3H^3O . *Cymylic Phenol*.—Of this homologue of phenol there are two modifications, viz. α thymol, existing in the volatile oils of thyme, horse-mint, and *Ptychotis Ajoowan* (v. 793); and β thymol, produced by fusing the potassium salt of cymyl-sulphurous or sulphocymylic acid with sodium hydrate, dissolving the fused mass in water, acidulating with sulphuric acid, and distilling in a current of steam; it then passes over as a yellowish viscid oil, lighter than water, which cannot be solidified either by cooling or by contact with a crystal of α thymol (R. Pott, *Zeitschr. f. Chem.* [2] v. 201;—H. Müller, *ibid.* 284).— α Thymol dissolves easily and completely in strong sulphuric acid at 40° – 50° , and the solution does not become turbid on dilution with water, because the thymol has been converted into an easily soluble sulpho-acid. β Thymol likewise dissolves easily in strong sulphuric acid, but only a small portion of it is thereby converted into a sulpho-acid even at 100° , and on addition of water, the greater part of the oil separates out unaltered. The aqueous solution neutralised with barium carbonate yields a barium salt, $(C^3H^3SO_2)^2Ba$, which crystallises in anhydrous needles. β Thymol dissolves easily in alkalis, and is precipitated therefrom by acids (Pott).

α Thymol heated with phosphoric anhydride is very easily and completely resolved into propylene and γ cresol (p. 597), the latter remaining in combination with phosphoric acid. α Thymol is therefore propyl-cresol, that is to say, propyl-methyl-phenol, $C^3H^3(OH) \begin{Bmatrix} C^3H^3 \\ C^6H^5 \end{Bmatrix}$ (Engelhardt & Latschinoff, *Zeitschr. f. Chem.* [2] v. 616); and as cymene is propyl-methyl-benzene, it follows also that β thymol has the constitution

of propyl-methyl-phenol (Pott). Probably one modification contains normal propyl, and the other isopropyl.

DERIVATIVES OF α THYMOL (Engelhardt a. Latschinoff, *Zeitschr. f. Chem.* [2] v. 43).

Methyl-thymol, $C^{10}H^{13}O(CH^3)$, is obtained by heating an alcoholic solution of equal quantities of thymol and potassium hydrate with excess of methyl iodide:

Precipitated from the alcoholic solution by water, treated with potash, and rectified, it forms an oily liquid having an aromatic odour and burning taste, boiling at 205° , insoluble in water, easily soluble in alcohol and ether. Sp. gr. = 0.941 at 18° .

Ethyl-thymol, $C^{10}H^{13}O(C^2H^5)$, is obtained by heating sodium-thymol in a sealed tube with ethyl iodide (Jungfleisch, *Bull. Soc. Chim.* [2] iv. 17), or by boiling an alcoholic solution of thymol and potassium hydrate with ethyl iodide (Engelhardt a. Latschinoff). It is a colourless mobile liquid having an aromatic odour, like that of carrots, and an extremely burning taste; insoluble in water, easily soluble in alcohol and ether; boils without decomposition at 222° ; oxidises slowly in the air. Potash does not attack it even when heated. With strong sulphuric acid it forms a soluble compound, probably analogous to that which is formed under similar circumstances from anisol (Jungfleisch).

Amyl-thymol, $C^{10}H^{13}O(C^5H^{11})$, obtained like the preceding, is an oily liquid insoluble in water, boiling with partial decomposition at 238° – 243° .

Benzoyl-thymol, $C^{10}H^{13}O(C^7H^5O)$, is formed by heating thymol with benzoyl chloride. After washing with soda-ley, &c., it forms an oil which distils without decomposition, does not become solid in a freezing mixture, but after keeping for some time solidifies to a crystalline mass which melts at the heat of the hand. It is soluble in ether, and when heated with ordinary sulphuric acid, is resolved into benzoic acid and α sulphothymolic acid.

Cymylene-thymol, $(C^{10}H^{13}O)_2(C^{10}H^{12})$. *Cumol-thymol*.—When 2 mol. thymol are heated with 2 mol. potassium hydrate and 1 mol. cymylene chloride, $C^{10}H^{12}Cl^2$ (prepared by the action of phosphorus pentachloride on cuminic aldehyde), potassium chloride separates, and the alcoholic solution mixed with water yields an oil, which is insoluble in potash, and solidifies after a while to a crystalline mass. Cymylene-thymol crystallises in rhombic tables melting at 157° .

When an alcoholic solution of 3 mol. thymol and 3 mol. potassium hydrate is boiled with 1 mol. *chloroform*, potassium chloride is formed, and the alcoholic filtrate mixed with water deposits a brown oil. *Benzotrichloride*, $C^6H_2Cl^3$, treated in like manner with potash and thymol, yields analogous products. The brown oil separated by water is resolved by heating with sulphuric acid into benzoic acid and α sulphothymolic acid.

Thymol Phosphate, $(C^{10}H^{13}O)^3(PO^3)$, is formed by heating thymol with phosphorus oxychloride: $3C^{10}H^{13}OH + POCl^3 = 3HCl + (C^{10}H^{13}O)^3PO$, and may be separated—by treating the product with potash, dissolving in ether, drying with calcium chloride, evaporating the ether, and heating the residual liquid to 200° —as a brownish oil which solidifies after some time to a crystalline mass. Thymol phosphate is likewise produced by heating 4 mol. thymol with 1 mol. phosphorus pentachloride. It is insoluble in water, easily soluble in ether and alcohol, and separates from solution in absolute alcohol by slow evaporation, in large translucent prisms having a fatty lustre. From an ethereal solution it crystallises in flat needles. It melts at 59° .

Sulphothymolic Acids. $C^{10}H^{12}SO^4 = C^{10}H^{12}\begin{Bmatrix} OH \\ SO^2H \end{Bmatrix}$. *Thymylsulphuric* or *Cymylsulphuric Acids*.—By treating thymol with sulphuric acid, Lallemand obtained a sulphothymolic acid which yielded soluble and well-crystallised barium and lead salts. Engelhardt a. Latschinoff have further examined the products of this reaction, and have obtained three isomeric sulphothymolic acids, which they distinguish by the prefixes α , β , γ ; also a disulphothymolic acid, $C^{10}H^{12}(SO^2H)^2$.

α *Sulphothymolic acid* is the chief product of the action of ordinary sulphuric acid on thymol at comparatively low temperatures, and is obtained quite pure, without the slightest admixture of the β and γ acids, by gradually adding sulphuric chloride, SO^2HCl , to thymol. Hydrochloric acid is then evolved, and the liquid on cooling solidifies to a crystalline mass of pure α sulphothymolic acid. A mixture of 60 grms. thymol and 40 grms. ordinary sulphuric acid, if left in a warm place (at about 50°), gradually becomes solid; and on dissolving the crystalline mass in water, filtering from unaltered thymol, agitating with ether, neutralising with barium carbonate, and evaporating, a large quantity of barium α sulphothymolate separates in

fine crystals. The last mother-liquors yield, together with crystals of the α salt, sparingly soluble laminae of totally different character; and by dissolving these crystals together with the mother-liquor in water, converting the dissolved barium salt into a potassium salt, and concentrating the aqueous solution, sparingly soluble laminae are obtained, consisting of the potassium salt of β sulphothymolic acid. On evaporating the mother-liquor of the first crystallisation to dryness, and dissolving the dry mass in boiling alcohol of 90 p. c., the alcoholic solution first yields on cooling, needles of the potassium salt of disulphothymolic acid, which is sparingly soluble in alcohol, and the mother-liquor of these needles yields by evaporation the easily soluble potassium salt of α sulphothymolic acid. The principal product of the reaction is a sulphothymolic acid, the β acid and disulphothymolic acid being obtained only in very small quantities.

The α sulphothymolates are easily soluble in water, and are coloured dark violet by ferric chloride. The potassium salt, $C^{10}H^{12}(OH)(SO^3K) + 2\frac{1}{2}H^2O$, crystallises from very concentrated aqueous solutions in beautiful transparent rhombic tables, or large prisms; from boiling alcohol, in which it is also very soluble, in large rhombic tables; the crystals effloresce in the air. The barium salt, $(C^{10}H^{12}SO^3)^2Ba + 4H^2O$, crystallises in flat transparent prisms decomposing at 100° . The lead salt, $(C^{10}H^{12}SO^3)^2Pb + 4H^2O$, crystallises from very strong aqueous solutions in stellate groups of needles; it is very soluble in boiling alcohol, and the solution solidifies on cooling to a mass of slender needles; the salt decomposes at 110° . The copper salt separates from alcoholic solution in indistinct crystalline crusts.

β Sulphothymolic acid is especially characterised by the sparing solubility of its potassium salt, $C^{10}H^{12}SO^3K + H^2O$, which crystallises from boiling aqueous solution in thin plates, and decomposes when heated above 115° . Its solution is coloured violet-blue by ferric chloride.

γ Sulphothymolic acid, $C^{10}H^{14}SO^4$, is produced, together with disulphothymolic acid, by heating thymol with a mixture of ordinary and fuming sulphuric acids, neutralising with barium carbonate, converting the resulting barium salts into potassium salts, and separating these salts by crystallisation from boiling alcohol, the disulphothymolate crystallising out first as the solution cools, and the mother-liquor yielding by evaporation granular masses of the γ sulphothymolate. This salt, $C^{10}H^{14}SO^3K + H^2O$, is very soluble in water and alcohol; does not decompose at 135° . The barium salt, $(C^{10}H^{14}SO^3)^2Ba + 3H^2O$, is more soluble in water than the α -sulphothymolate, and crystallises therefrom in tufts of needles; does not decompose at 135° .

Potassium Disulphothymolate, $C^{10}H^{11}(OH)(SO^3K)^2 + 1\frac{1}{2}H^2O$, is very soluble in water, sparingly soluble in cold, more easily in boiling alcohol, and crystallises from the boiling alcoholic solution in long slender shining needles which on exposure to the air immediately crumble to a white powder.

Methyl-sulphothymolic acid, $C^{11}H^{13}SO^4 = C^{10}H^{12}\left\{\begin{smallmatrix} OCH^3 \\ SO^3H \end{smallmatrix}\right.$, is obtained by the action of sulphuric acid on methyl-thymol. Its barium salt, $(C^{11}H^{13}SO^3)^2Ba + 3H^2O$, is very soluble in boiling water, and crystallises in small nodules on cooling.

Ethyl-sulphothymolic Acid, $C^{12}H^{15}SO^4 = C^{10}H^{12}\left\{\begin{smallmatrix} OC^2H^5 \\ SO^3H \end{smallmatrix}\right.$.—Of this acid there are two modifications, α and γ , obtained by the action of ethyl iodide on the salts of the corresponding sulphothymolic acids. The potassium salts of the two acids have the same composition, $C^{10}H^{12}(OC^2H^5)(SO^3K)$. The α salt crystallises in thin tables, the γ salt in flat needles; both dissolve sparingly in cold, easily in boiling water, and resemble each other closely in other respects; so likewise do all the other corresponding salts of the two acids. The solutions of the potassium salts mixed with barium chloride yield precipitates of the barium salts, which crystallise from boiling water, the α salt in thin laminae, the γ salt in six-sided tables, both containing $(C^{12}H^{15}SO^3)^2Ba + 3H^2O$. Ethyl-thymol dissolves when heated with ordinary sulphuric acid, and by neutralising the solution with barium carbonate, two salts are obtained, the less soluble of which is the α ethyl-sulphothymolate, while the more soluble is not isomeric with it.

α Amyl-sulphothymolic acid, $C^{15}H^{23}SO^4 = C^{10}H^{12}\left\{\begin{smallmatrix} OC^5H^{11} \\ SO^3H \end{smallmatrix}\right.$, is obtained by heating the potassium salt of α sulphothymolic acid with potash and amyl-iodide. The potassium salt, $C^{15}H^{23}SO^3K$, crystallises in needles easily soluble in water. The barium salt, $(C^{15}H^{23}SO^3)^2Ba + 3H^2O$, forms flat needles sparingly soluble in cold, more easily in boiling water. By dissolving amyl-thymol in warm sulphuric acid, neutralising with barium carbonate, and evaporating, flat needles of the same salt are obtained, and the mother-liquor yields a more soluble salt having the same composition.

***a* Benzoyl-sulphothymolic Acid.** $C^{10}H^{15}SO^5 = C^{10}H^{12}\left\{\begin{smallmatrix} OC^7H^5O \\ SO^3H \end{smallmatrix}\right.$.—The potassium salt of this acid, $C^{10}H^{11}SO^4K + 2H^2O$, is obtained by heating the *a* sulphothymolate to 125° with benzoyl chloride. It is slightly soluble in cold, more soluble in boiling water, and crystallises on cooling in flat shining needles. The other *a* benzoyl-sulphothymolates are also slightly soluble in cold, more soluble in hot water, and are prepared from the potassium salt by double decomposition. The *barium* and *lead* salts crystallise in flat needles containing 5 mol. water; the *calcium* salt in small tables containing 4 mol. water; the *silver* salt in shining needles.

The potassium salt of *γ* benzoyl-sulphothymolic acid is very much like the *a* salt, but contains 3 mol. water.

TIN. Blocks of Banka tin exposed to the open air at St. Petersburg in the cold winter of 1867–1868 acquired a crystalline structure and partly crumbled to a granulo-crystalline powder. The internal cavities became lined with a metallically lustrous film, while the crystalline structures themselves appeared dull (Fritzsche, *Phil. Mag.* [4] xxxviii. 207).

Calvert a Johnson (*Chem. Soc. J.* [2] iv. 435) have examined the action of sulphuric acid of different strengths upon tin, with the following results. By two hours' action of 50 c. c. acid on 1 c. c. metal, the following quantities were dissolved:

	Grams.		Grams.
By H^2SO^4 at 150°	3.010	By $H^2SO^4.3H^2O$ at 130°	0.215
„ $H^2SO^4.H^2O$ at 150°	0.640	„ $H^2SO^4.4H^2O$ „	0.140
„ $H^2SO^4.2H^2O$ at 150°	0.470		

The action of pure hydrogen sulphate, H^2SO^4 , is attended with evolution of sulphurous oxide and separation of sulphur; with $H^2SO^4.H^2O$ sulphurous oxide is likewise evolved; with $H^2SO^4.2H^2O$ hydrogen sulphide goes off, together with the sulphurous oxide; and with the two weaker hydrates hydrogen sulphide is the chief gaseous product.

Alloys. Riche (*Compt. rend.* lxxvii. 1138) has examined the physical properties of alloys of tin and copper in various proportions from Sn^3Cu to $SnCu^{13}$ (gun-metal). With regard to density, it appears that the contraction increases pretty regularly from the alloys richest in tin to the alloy $SnCu^2$, but that it then increases very rapidly, attaining its maximum in the alloy $SnCu^3$. The density then diminishes down to the alloy $SnCu^4$, beyond which it again regularly increases, but only so far that the density of the alloy richest in copper still remains less than that of the alloy $SnCu^3$. This alloy differs in its properties from all the rest, being so brittle that it may be pulverised in a mortar, and forming bluish crystalline grains not resembling either tin or copper. The solidifying point of the alloys $SnCu^2$ and $SnCu^4$ is intermediate between the melting point of antimony and the boiling point of cadmium.

Chlorides. 1. *Stannous Chloride*, $SnCl^2$ (Gerlach, *Dingl. pol. J.* clxxxvi. 131; *Bull. Soc. Chim.* [2] ix. 248; *Jahresh.* 1867, 272).—Well-defined crystals of this salt, as well as the needle-shaped crystals often found in commerce, and the lamino-scaly crystals which separate from solutions containing a considerable proportion of stannic oxide, all have the composition $SnCl^2.2H^2O$. Stannous chloride likewise crystallises with the same amount of water from a solution containing equivalent quantities of stannous and stannic chlorides (contrary to former statements, v. 807). The specific gravities of aqueous solutions of stannous chloride are given in the following table, in which *p* denotes the percentage of crystallised salt, $SnCl^2.2H^2O$, and *d* the specific gravity at 15° :

<i>p</i>	<i>d</i>	<i>p</i>	<i>d</i>	<i>p</i>	<i>d</i>
0	1.0000	30	1.2300	60	1.6823
5	1.0331	35	1.2779	65	1.6598
10	1.0684	40	1.3298	70	1.7452
15	1.1050	45	1.3850	75	1.8399
20	1.1442	50	1.4451		
25	1.1855	55	1.5106		

On the reaction of stannous chloride with arsenious and arsenic acid, see **ARSENIC** (pp. 220, 222); on its reaction with metallic solutions and sulphurous acid (p. 1065).

Stannic Chloride, SnCl_4 (Gerlach, *Dingl. pol. J.* clxxviii. 49; *Bull. Soc. Chim.* [2] iv. 483; *Jahresb.* 1865, p. 237).—The specific gravity of the anhydrous chloride is 2.234 at 15° . When it is rapidly mixed with water, the liquid becomes heated to the boiling point; on gradual addition of water, a point is reached at which the hot aqueous solution is denser than the undissolved aqueous chloride. The dissolution is accompanied by a diminution of volume greater than that hitherto observed in any other mixture. In the following table, P denotes the percentage of anhydrous chloride in the solution; D the specific gravity of the solution at 15° ; V the volume of 100 pts. by weight, that of 100 parts by weight of water being = 100; V' the volume which 100 parts by weight would occupy if no contraction took place; V'' the volume of the mixture, that of the sum of the constituents being = 100.

P	D	V	V'	V''
0	1.000	100.00	100.00	100.00
10	1.082	92.42	94.48	97.82
20	1.174	85.18	88.95	95.76
30	1.279	78.19	83.43	93.72

Gerlach has obtained the hydrates $\text{SnCl}_4 \cdot 3\text{H}_2\text{O}$, $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$, and $\text{SnCl}_4 \cdot 8\text{H}_2\text{O}$ in the crystalline form. When 1 mol. stannic chloride (259.48 pts.) is mixed with 1 mol. water (18 pts.), two thirds of the stannic chloride remain unaltered, whilst the remaining third forms the hydrate $\text{SnCl}_4 \cdot 3\text{H}_2\text{O}$, which sinks in the excess of stannic chloride. When 1 mol. stannic chloride is mixed with 2 mol. water, the whole solidifies while still hot to a solid mass enclosing $\frac{1}{3}$ of the chloride in the anhydrous state. 1 mol. stannic chloride dissolves in 3 mol. water with great evolution of heat, the temperature rising to the boiling point, and forms a clear liquid which deposits the hydrate $\text{SnCl}_4 \cdot 3\text{H}_2\text{O}$ at 60° , and solidifies to a mass when quite cold. The fumes which stannic chloride emits in moist air, and the efflorescences which form on the edges of vessels containing it, likewise consist of the trihydrated salt. A mixture of stannic chloride with 4 mol. water yields transparent pointed crystals having the composition $\text{SnCl}_4 \cdot 4\text{H}_2\text{O}$; these however are regarded by Gerlach as consisting of the trihydrate with enclosed solidified mother-liquor. The pentahydrate, $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$, separates gradually from duly concentrated solutions in white, turbid, very deliquescent monoclinic crystals which melt at a gentle heat. Less concentrated solutions yield at very low temperatures large transparent crystals of the octohydrate, $\text{SnCl}_4 \cdot 8\text{H}_2\text{O}$,* still more deliquescent than the pentahydrate. This latter is regarded by Gerlach as the best adapted for industrial use. The following table (p. 1094) exhibits the specific gravities (D) of aqueous solutions containing the percentages (P) of crystallised pentahydrated stannic chloride, for the temperature of 15° .

The aqueous solution of stannic chloride acts as an acid towards most metallic oxides; it takes up 1 mol. stannic hydrate, forming a soluble oxychloride, and reacts in a similar manner with other oxides soluble in hydrochloric acid. Recently prepared solutions of stannic chloride are not coloured by stannous chloride, but those which have been kept for some time acquire thereby a yellow colour, arising, according to Gerlach, from the formation of stannic oxychloride. In a concentrated limpid solution of stannic oxychloride, stannous chloride dissolves with dark brown colour (Gerlach).

A solution containing the chlorides of sodium, potassium, lithium, cesium, and rubidium, together with free hydrochloric, gives with stannic chloride a crystalline precipitate consisting of nearly pure cesium stannochloride, $\text{Cs}_2\text{Sn}^{IV}\text{Cl}_6$ or $2\text{CsCl} \cdot \text{SnCl}_4$ (Sharples, *Sill. Am. J.* [2] xlvii. 178; *Zeitschr. f. Chem.* [2] v. 406).

* Müller (*Zeitschr. f. Chem.* [2] i. 445) obtained from a solution of stannic chloride prepared by treating stannous chloride with nitromuriatic acid and exposed to a winter temperature, transparent colourless rhombic octahedrons of the salt $\text{SnCl}_4 \cdot 9\text{H}_2\text{O}$, which deliquesced when heated above 10° .

Density of Aqueous Solutions of $\text{SnCl}^4 \cdot 5\text{H}^2\text{O}$ at 15° .

Stannic chloride added to *amyl alcohol* cooled by a freezing mixture, unites with it, producing the compound $\text{SnCl}^4 \cdot 2\text{C}^3\text{H}^{12}\text{O}$, which forms colourless tabular deliquescent crystals, instantly resolved by water into stannous chloride, hydrochloric acid, and amyl alcohol. The crystals heated to 100° are decomposed, chiefly in the manner represented by the equation: $2(\text{SnCl}^4 \cdot 2\text{C}^3\text{H}^{12}\text{O}) = \text{SnCl}^4 \cdot 3\text{H}^2\text{O} + \text{SnCl}^2 \cdot \text{H}^2\text{O} + 3\text{C}^3\text{H}^{10} + \text{C}^3\text{H}^9\text{Cl}^2$ (Bauer a. Klein, *Zeitschr. f. Chem.* [2] iv. 370).

Iodide. Crystallised stannic iodide is most easily obtained by gradually adding 4 pts. of iodine in small portions to 1 pt. of tin-foil immersed in 6 pts. carbon bisulphide contained in a closed vessel and well cooled, decanting the solution as soon as it acquires a pure yellow colour, and leaving it to evaporate; 1 pt. carbon bisulphide dissolves at ordinary temperatures 1.45 pt. stannic iodide (R. Schneider, *Jahresb.* 1866, p. 229).

Stannic Oxide, Acids, and Salts. The distinguishing characteristics of stannic and metastannic acids have been further examined by Barfoed (*J. pr. Chem.* ci. 368; *Jahresb.* 1867, p. 267). *Reaction with Caustic Soda.*—Ordinary or *a*-stannic acid dissolves easily in soda-ley, and is not precipitated by the excess of the alkali. Meta- or *b*-stannic acid is completely precipitated by soda-ley from a moderately dilute acid solution, in the form of sodium metastannate.* The precipitate is easily soluble in water, insoluble in dilute soda-ley and in weak spirit. When dried it forms white, gummy granules, and when pulverised is easily dissolved by treatment with hydrochloric acid and subsequent addition of water. Sodium metastannate precipitated by soda-ley from the hydrochloric solution of metastannic acid, washed with alcohol and dried at 100° , was found to have the composition $\text{Na}^2\text{O} \cdot 9\text{SnO}^2 + 8\text{H}^2\text{O}$.

Reaction with Hydrochloric Acid.—The hydrochloride of *a*-stannic acid dissolves easily in hydrochloric acid of sp. gr. 1.1. When this solution, which alters but slowly, is distilled, the whole of the tin passes over as tetrachloride. The hydrochloride of metastannic acid is insoluble in hydrochloric acid of sp. gr. 1.1, and is easily purified by washing with such acid. The recently prepared perfectly pure compound forms a colourless solution; the yellow colour which it commonly exhibits arises partly from residual nitric acid (which sets chlorine free), partly from iron and other impurities. The solution decomposes rather quickly, and with greater facility as it is more dilute

* According to Frémy, sodium metastannate dissolves slowly, but completely, in water (v. 821).

and contains less acid; the solid compound likewise undergoes a similar decomposition and becomes insoluble. By strong hydrochloric acid, recently prepared and still moist metastannic acid is gradually converted into stannic acid; after drying at 100° it undergoes the same change, but less easily.* The proportion of metastannic acid thus converted increases with the quantity of hydrochloric acid, the time of contact, and the temperature. Consequently the hydrochloric acid solution of metastannic acid always contains more or less stannic acid, which may be separated in the manner above mentioned; and herein may be found an explanation of the fact that the hydrochloric acid solution of metastannic acid likewise yields by distillation a certain quantity of stannic chloride.

Reaction with Hydrogen Sulphide.—The precipitates formed by hydrogen sulphide in both modifications of stannic acid are always mixtures of stannic sulphide with *a* or *b* stannic hydrate: they are not, however, identical. Recently prepared, concentrated and acid solutions of stannic chloride form a light yellow precipitate which retains its colour unaltered; non-acid solutions yield a reddish-yellow, and very dilute solutions a white precipitate, which turns yellow only when washed. All these precipitates in the moist state, after washing, contain, besides stannic sulphide, variable quantities of *a*-stannic acid; they dissolve easily in alkaline leys and in warm dilute hydrochloric acid, the solution exhibiting all the reactions of *a*-stannic acid. During drying they continually give off hydrogen sulphide, assume a dark brown or nearly black colour, and are then no longer perfectly soluble in soda-ley. Metastannic acid is very slowly attacked by hydrogen sulphide. Dilute hydrochloric acid solutions of it form, with hydrogen sulphide, a white precipitate consisting essentially of metastannic hydrate; concentrated solutions, a yellow-brown precipitate; both precipitates, when kept for 24 hours in closed vessels, assume a dark brown colour, and when dried turn black and give off hydrogen sulphide. Since, when metastannic acid is dissolved in strong hydrochloric acid, a certain portion, variable according to circumstances, is converted into stannic acid, it follows that these precipitates are mixtures of those which would be produced from pure stannic and pure metastannic acid; they therefore contain stannic and metastannic acid together with stannic sulphide, and are on the average less rich in sulphur than those which are formed from stannic acid. When treated with soda-ley, they leave a white residue of sodium metastannate, and likewise yield with colourless ammonium sulphhydrate a white precipitate, which disappears on heating the liquid. In warm potash, ammonia, and hydrochloric acid they dissolve with moderate facility with aid of heat.

From the preceding reactions, Barfoed regards treatment with soda-ley as the best means both for the qualitative detection and for the separation of the two stannic acids. For quantitative estimation he determines the total quantity of tin in one aliquot part of the solution, and the amount of metastannic acid in another by precipitation with soda-ley. In the filtrate and wash-water thereby obtained, the *a*-stannic acid may, for verification, be separated by hydrogen sulphide from the solution acidulated with hydrochloric acid, and estimated by known methods.

Musculus (*Compt. rend.* lxx. 961) describes certain hydrates intermediate between ordinary stannic hydrate, ($\text{SnO}_2 \cdot \text{H}_2\text{O}$), and metastannic hydrate, ($\text{Sn}^{\text{AO}} \cdot 5\text{H}_2\text{O}$), and produced from the former by keeping under water. Recently prepared stannic hydrate (precipitated from stannic chloride by ammonia) dissolves easily in strong nitric and hydrochloric acid, also in caustic potash, and is precipitated by a large excess of potash as a crystalline powder. After several hours immersion in water, it loses its solubility in nitric acid, and when treated in potassic solution with excess of potash, yields an amorphous precipitate (second hydrate). After several days it becomes insoluble in hydrochloric acid, but still remains soluble in potash (third hydrate).

From metastannic acid, into which these two hydrates are ultimately converted, they are distinguished by the fact that they still dissolve in strong hydrochloric and nitric acids in presence of alkaline chlorides. Metastannic acid, treated with boiling concentrated potash-ley, yields at first the potassium salts corresponding to the third and second hydrate, which separate in consequence of their sparing solubility; it is only when the solution has become very concentrated that crystals of ordinary potassium stannate are formed. The potassium salt of the second hydrate contains 2 at. tin to 1 at. potassium; that of the third hydrate 3 at. tin to 1 at. potassium; the corresponding acids are therefore represented by the formulae:

* On the conversion of stannic into metastannic acid, see v. 820.

When metastannic hydrate is boiled with concentrated hydrochloric acid, and the liquid separated from the precipitate is saturated with hydrochloric acid gas, a precipitate is formed containing the hydrate $\text{Sn}^2\text{H}^2\text{O}^2$; the remaining acid solution leaves on evaporation a crystalline, very deliquescent acid, easily soluble in ether, and consisting, according to Musculus, of a mixture of crystallised hydrated stannic chloride, and the hydrochloride of the hydrate $\text{Sn}^2\text{H}^2\text{O}^2$. From these observations Musculus infers the existence of a series of polystannic acids analogous to the polysilicic acids.

Sodium Stannate. $\text{Na}^2\text{Sn}^2\text{O}^2$ or $\text{Na}^2\text{O} \cdot \text{SnO}^2$.—Of this salt three hydrates have been previously obtained, containing 3, 8, and 9 mol. water (v. 819). Another hydrate, $\text{Na}^2\text{SnO}^3 + 10\text{H}^2\text{O}$, crystallises in large prisms from dilute solution by evaporation at a low temperature. These crystals form only in pure solutions, especially in such as are free from excess of soda; they are very efflorescent, and decompose in aqueous solution at 80° , with separation of stannic hydrate; addition of soda prevents this decomposition (Scheurer-Kestner, *Bull. Soc. Chim.* [2] vii. 399).

Respecting stannates containing platinum, see p. 1077.

Selenides (Schneider, *Pogg. Ann.* cxxvii. 624; *Bull. Soc. Chim.* [2] vi. 449; *Jahresh.* 1866, p. 227).—The monoselenide or stannous selenide, SnSe , may be obtained crystallised and quite pure, by heating finely pulverised selenium with fused anhydrous stannous chloride till the mixture appears transparent in thin layers: $2\text{SnCl}^2 + \text{Se} = \text{SnSe} + \text{SnCl}^4$. Stannic chloride then volatilises, and the stannous selenide, which remains dissolved in the excess of stannous chloride, crystallises out on cooling. The product which Uelmann obtained (v. 821) by fusing 3 pts. tin with 2 pts. selenium generally contains free tin; it may be converted into the pure monoselenide by fusion with stannous chloride as above.

Stannous selenide crystallises in prisms or laminæ resembling stannous sulphide, and probably isomorphous with it; the crystals have a sp. gr. of 5.24, a steel-grey colour and metallic lustre; may be heated in a close vessel or in a stream of hydrogen without alteration, but are slowly converted into stannic oxide when heated in the air, and are scarcely attacked by aqueous soda or ammonia, even at the boiling heat (in which respect they differ from the monoselenide prepared in the wet way), but are dissolved with red colour by the sulphides and selenides of the alkali-metals. Boiling hydrochloric acid dissolves them slowly, with solution of hydrogen selenide; strong nitric acid at the boiling heat colours them brown-red from separation of selenium, and ultimately converts them into selenious and selenic acid; nitromuriatic acid dissolves them with facility.

An intimate mixture of 2 mol. stannous selenide (4 pts.) and 2 mol. iodine (5 pts.) liquefies at a gentle heat, and solidifies to a red-brown mass, which is dissolved by carbon bisulphide to a yellowish liquid, with a residue of stannic selenide (with small quantities of stannous selenide and free selenium). The solution when left to evaporate first yields dark red crystals of selenium; then, to the last drops, chrome-red octahedral crystals of stannic iodide: $2\text{SnSe} + \text{I}^4 = \text{SnI}^4 + \text{SnSe}^2$. With twice the quantity of iodine the reaction takes place with equal facility, and without separation of iodine: $\text{SnSe} + \text{I}^4 = \text{SnI}^4 + \text{Se}$; on treating the product with carbon bisulphide, the greater part of the selenium remains undissolved. A solution of iodine in carbon bisulphide acts on stannous selenide in the same way at ordinary temperatures, the excess of iodine remaining in solution uncombined, together with selenium; compounds of selenium and iodine cannot therefore be obtained in this manner. Bromine acts on stannous selenide in a similar manner to iodine, combining with it in the cold with a hissing noise and rise of temperature; more quietly when added with agitation to the selenide immersed in carbon bisulphide. The products are stannic bromide and stannic selenide, or stannic bromide and selenium, according to the proportions used: $2\text{SnSe} + 2\text{Br}^2 = \text{SnBr}^4 + \text{SnSe}^2$; and $\text{SnSe} + 2\text{Br}^2 = \text{SnBr}^4 + \text{Se}$. When more than 2 mol. bromine are used to 1 mol. stannous selenide, selenium bromides are likewise formed.

The biselenide or stannic selenide, SnSe^2 , is very easily decomposed by heat, and cannot therefore be prepared either by heating a mixture of its elements, or by a process similar to that generally used for preparing the bisulphide (mosaic gold); the compound described by Little (v. 882) as biselenide of tin was probably only monoselenide. The biselenide may however be prepared by means of the above-mentioned reaction between iodine and the monoselenide. 5 pts. of iodine are triturated to a homogeneous mixture with 8 to 10 pts. of crystallised stannic iodide; this is ultimately mixed by gentle trituration with 4 pts. of levigated stannous selenide, and carbon bisulphide is added, with rapid stirring, in sufficient quantity to form a pasty mass, which is then treated with a large quantity of carbon bisulphide to

dissolve the stannic iodide. After washing with carbon bisulphide, the stannic selenide remains as an indistinctly crystalline powder, which when dried has a specific gravity of 4.85, and a dark red-brown colour, becoming darker at 100°. It is not attacked by water or dilute acids, scarcely by strong boiling hydrochloric acid; reacts like the monoselenide with nitric and nitromuriatic acid. Heated with strong sulphuric acid, it forms an olive-green solution, from which, when poured into a large quantity of water, selenium is separated as a red powder, while stannic sulphate remains in solution. In caustic fixed alkalis and ammonia the biselenide dissolves at ordinary temperatures, forming blood-red solutions, from which it is precipitated by acids. 1 mol. stannic selenide gently heated with 2 mol. iodine melts to a dark red liquid, which, when further heated, yields a sublimate of iodine and afterwards of stannic iodide, and after solidification may be resolved by carbon bisulphide into soluble stannic iodide and a residue of selenium: $\text{SnSe}^2 + 2\text{I}^2 = \text{SnI}^4 + \text{Se}$. A solution of iodine in carbon bisulphide acts on stannic selenide in the same manner. Bromine also produces a similar reaction.

Sulphides. The statement of Proust (v. 823) that stannic sulphide and chloride are formed by the action of sulphur on fused stannous chloride does not appear to be correct. The reaction is in fact analogous to that which takes place with selenium (p. 1096), the products being stannic chloride, which volatilises, and stannous sulphide, which remains dissolved in the excess of stannous chloride, and separates in crystals on cooling (Schneider).

Platinum-tin Compounds (Schneider, *Pogg. Ann.* cxxxvi. 105; *Zeitschr. f. Chem.* [2] v. 613).—When a solution of platonic chloride containing 0.01 grm. platinum in a cubic centimetre is mixed with a moderately strong solution of stannous chloride in hydrochloric acid, the mixture, if kept in a closed vessel, gradually turns dark brown, and yields a brown precipitate with ammonia. To precipitate all the platinum requires at least 3 mol. stannous chloride to 1 mol. platonic chloride. The reaction may perhaps be supposed to take place as represented by the equation:

assuming the formation of a hypoplatinous oxide containing only half as much oxygen as platinum oxide. The compound $\text{PtO} \cdot 3\text{SnO}^2$ or $\text{Pt}^2\text{O} \cdot 3\text{SnO} \cdot 3\text{SnO}^2$ may accordingly be designated as *hypoplatinous-stannous stannate* (Schneider calls it *zinnsaures Platinoxydul-zinnoxidul*). The brown compound treated with soda-ley does not, however, yield the supposed oxide of platinum, but a black substance, $\text{Na}^2\text{PtSn}^2\text{O}^6$ or $\text{PtO} \cdot \text{Na}^2\text{O} \cdot 2\text{SnO}^2$, which may be called *sodio-hypoplatinous stannate*. Hypoplatinous-stannous stannate, fused with potassium carbonate and sulphur, yields potassio-platinnous sulphostannate, $\text{K}^2\text{Pt}^2\text{Sn}^4\text{S}^6$ (p. 1077). The salt thus obtained was formerly supposed by Schneider to contain oxygen as well as sulphur; but more recent experiments have shown that this supposition is incorrect.

TITANIUM. *Titanio-phosphoric chloride*, $\text{Ti}^4\text{P}^3 = \text{TiCl}^4 \cdot \text{PCl}^3$, analogous to the tin compound, $\text{SnCl}^4 \cdot \text{PCl}^3$, described by Casselmann (v. 809), is produced, according to Tüttschew (*Ann. Ch. Pharm.* cxli. 111), by heating an intimate mixture of 1 pt. titanic oxide, TiO^2 (15 grm.) and 3 mol. phosphorus pentachloride (115 grm.) in a retort, continuing the heat for a considerable time after the reaction is completed, in order to volatilise the phosphorus oxychloride which is likewise formed: $\text{TiO}^2 + 3\text{PCl}^3 = \text{TiCl}^4 \cdot \text{PCl}^3 + 2\text{POCl}^3$. It is also formed, according to Weber (*Pogg. Ann.* cxxii. 452), by the direct mixture of the component chlorides, or by passing their vapours together through a red-hot glass tube; but the product thus obtained is contaminated with portions of the uncombined chlorides. It may be obtained pure by passing chlorine into a mixture of phosphorus trichloride with excess of titanic chloride, and heating the product gently towards the end in a stream of chlorine.

Titanophosphoric chloride is a lemon-yellow, indistinctly crystalline mass, which dissolves without decomposition in ether, and remains as a gummy mass on evaporating the solution; it is also dissolved in small quantity by phosphorus oxychloride, but cannot easily be separated from the solution. Water and moist air decompose it rapidly. Placed under a receiver with water and quick lime, it leaves, after a few days, titanic hydrate which is quite free from phosphoric acid, and, after remaining for some time, contains only a trace of chlorine (Tüttschew). According to Weber, it volatilises when heated, without previous fusion, and condenses to a yellow powder on cooling. It is very hygroscopic, and dissolves in dilute acids to a yellow liquid, which after some time deposits a gelatinous precipitate.

The compound $\text{TiCl}^4 \cdot \text{POCl}^3$ is formed by dropping phosphorus oxychloride into

excess of titanic chloride, and is obtained pure by warming the solidified mixture till it melts completely, and decanting the portion which remains liquid after cooling, from the crystalline mass which constitutes the compound in question. It is colourless, easily fusible, and very hygroscopic (Weber).

A mixture of titanic chloride and sulphur chloride, saturated with chlorine gas and gently warmed in a stream of chlorine, yields *titano-sulphurous chloride*, $2\text{TiCl}_4 \cdot \text{SCl}_2$, as a sulphur-yellow powder, which is decomposed at a stronger heat, is very deliquescent, and dissolves in dilute nitric acid, with formation of sulphuric, hydrochloric, and titanic acids. The compound which H. Rose obtained (v. 538) appears to have been merely a mixture (Weber).

Titanic Hydrates (Tüttschew, *loc. cit.*).—The hydrate obtained by the action of moist air on titanophosphoric chloride has, after drying over oil of vitriol, the composition of the normal hydrate, or titanic acid, TiH^4O^5 . At 110° – 120° it gives off 15.50 p. c. water, and is converted into the first anhydride, TiH^2O^3 . In appearance and properties the normal hydrate resembles the hydrate obtained by boiling with sulphuric acid, which after drying over oil of vitriol has the same composition. The latter (*b*-titanic acid, metatitanic acid, or metatitanic hydrate) heated to 120° , leaves the hydrate $\text{Ti}^3\text{H}^3\text{O}^{10}$, and at 140° the hydrate $\text{Ti}^3\text{H}^4\text{O}^8$, previously observed by Demoly. The hydrate obtained by precipitation with ammonia, to which Demoly assigned the formula $3\text{TiO}_2 \cdot 5\text{H}_2\text{O}$ or $\text{Ti}^3\text{H}^{10}\text{O}^{11}$, was found by Tüttschew, after drying in a vacuum, to contain $\text{Ti}^3\text{H}^5\text{O}^8$. At 140° this hydrate is converted into $\text{Ti}^3\text{H}^2\text{O}^3$. From these results Tüttschew infers the existence of a series of polytitanic acids analogous to the polysilicic acids, and formed from normal titanic acid according to the general equation:

The following table exhibits the composition of the hydrates of titanic acid, as determined by the observations of different chemists, by no means always accordant:

a Titanic acid (precipitated by ammonia).

Air-dried	$\text{TiO}_2 \cdot \text{H}_2\text{O} = \text{Ti}^3\text{H}^5\text{O}^8$	Merz.
Dried over sulphuric acid, or at 60°	$2\text{TiO}_2 \cdot \text{H}_2\text{O} = \text{Ti}^2\text{H}^2\text{O}^3$	Merz.
" at 140°	$3\text{TiO}_2 \cdot 2\text{H}_2\text{O} = \text{Ti}^3\text{H}^5\text{O}^8$	Demoly, Tüttschew.
" at 100°	$3\text{TiO}_2 \cdot \text{H}_2\text{O} = \text{Ti}^3\text{H}^2\text{O}^3$	Merz.

Hydrate formed by moist air from Titanophosphoric chloride.

Dried over sulphuric acid	$\text{TiO}_2 \cdot 2\text{H}_2\text{O} = \text{TiH}^4\text{O}^4$	Tüttschew.
" at 110° – 120°	$\text{TiO}_2 \cdot \text{H}_2\text{O} = \text{TiH}^2\text{O}^3$	Tüttschew.

For the preparation of pure titanic acid, and its separation from zirconia and ferric oxide, the following method is given by Streit a. Franz (*J. pr. Chem.* cviii. 65; *Zeitschr. f. Chem.* [2] vi. 256). Finely pulverised and levigated rutile is intimately mixed with three times its weight of potassium carbonate, and fused in a Hessian crucible, and the fused mass is poured in a thin layer upon an iron plate. It is then finely pulverised and exhausted with cold water, whereby silicate and tungstate of potassium are removed, while potassium titanate and ferric oxide remain undissolved. The residue is dissolved in crude hydrochloric acid, rise of temperature being prevented as far as possible; the resulting solution is generally somewhat clouded

* *Jahresb.* 1866, p. 197.

† *Ibid.* 1849, p. 270.

‡ *Ann. Ch. Pharm.* lli. 268.

with silica. Any ferric oxide contained in the solution is reduced by hydrogen sulphide, and the excess of that reagent is driven off at about 45° . The liquid is then filtered, mixed with $\frac{1}{2}$ to $\frac{2}{3}$ of its volume of acetic acid of sp. gr. 1.038, and $\frac{1}{2}$ of its volume of dilute sulphuric acid containing 1 vol. hydrogen sulphate to 5 vol. water, and boiled. After eight or ten hours' boiling, the whole of the titanic acid is precipitated quite white and free from iron. It is easily washed, but when nearly pure is slow in settling down; its deposition may however be accelerated by adding acetic acid to the liquid.

When solutions of ferruginous titanic acid are boiled, the titanium is precipitated as a very acid ferric titanate; acetic acid prevents the formation of this compound; so likewise do tartaric, citric, oxalic acid, &c. Sugar does not prevent the separation of the ferric titanate on boiling, but from a ferruginous solution of titanic acid mixed with sugar, ammonia throws down pure titanic acid. Any zirconia that may be present remains, together with the iron, in the solution containing sulphuric and acetic acids.

TOLALLYL-SULPHIDE. $C^{26}H^{20}S^2$.—This compound, the sulphur analogue of oxylepidine, is produced, together with thionessal, by the dry distillation of sulphobenzide, or of benzylic sulphide or bisulphide (p. 1087).

TOLANE. C^8H^{10} (Limpricht a. Schwanert, *Ann. Ch. Pharm.* cxlv. 330).—A hydrocarbon produced by heating toluylene bromide to 130° for ten or twelve hours with alcoholic potash:

also, according to Zinin (*Zeitschr. f. Chem.* [2] iv. 718), when the product of the action of phosphorus pentachloride on deoxybenzoin, $C^8H^{10}O$, is distilled with potash or heated to the boiling point:

and

Tolane dissolves very easily in ether or in hot alcohol, and crystallises from ether in large transparent crystals, from alcohol in long prisms or laminae; melts at 60° , and distils without decomposition at a higher temperature. *Tolane bromide*, $C^8H^{10}Br^2$, is precipitated on mixing the ethereal solution of tolane with bromine, and is likewise formed from brominated toluylene bromide by distillation or by heating with water to 140° . It crystallises from hot alcohol in small flat needles or nacreous scales, dissolves with difficulty in alcohol and in ether, melts at 200° – 205° , and is partly resolved by distillation into bromine, hydrobromic acid, needles melting at 85° , and a non-crystallising oil. Heated to 120° with alcoholic potash, it yields tolane and acetic aldehyde, as shown by the following equation:

TOLONITRILE or **TOLYL CYANIDE**, C^8H^7N = $C^8H^7.CN$, is produced by dehydration of tolyl-formamide: $N(CHO)(C^8H^7)H - H^2O = C^8H^7N$. By boiling with soda-ley it is converted into toluic acid.

TOLUIC ACID. The formula $C^8H^6O^2$ includes the two following acids:

The latter has the constitution of phenyl-acetic acid, and admits of no further modification; but the former admits of three isomeric modifications, ortho-, meta-, and para-, according to the relative positions of the groups CH^3 and CO^2H .

Ordinary toluic acid (v. 863) is produced by oxidation of coal-tar xylene with dilute nitric acid. Now Fittig has shown that coal-tar xylene is a mixture of meta-xylene (identical with that which is obtained by distilling mesitylenic acid with lime) and paraxylene, which is identical with artificially prepared methyl-toluene, the former greatly predominating (see *BENZENE, HOMOLOGUES* OF, p. 293); further, that when this mixed hydrocarbon is treated with dilute nitric acid, the paraxylene or methyl-toluene is alone oxidised, yielding ordinary toluic acid and terephthalic or

paraphthalic acid. Hence it appears that ordinary toluic acid, which melts at 176° , is paratoluic acid. Orthoxylene, obtained by distilling paraxylic acid with lime (p. 293), treated with dilute nitric acid, is slowly oxidised to toluic acid, which is slightly soluble in cold water, moderately soluble in boiling water, and crystallises from a dilute solution in splendid, long, transparent, specular crystals melting at 102° ; this is orthotoluic acid; its calcium salt, $(C^6H^4O^2)^2Ca + 2H^2O$, and barium salt, $(C^6H^4O^2)^2Ba$, are very soluble in water, and crystallise in slender needles (Bieber a. Fittig, *Zeitschr. f. Chem.* [2] vi. 496). Lastly, by oxidising monobromoxylene (from coal-tar xylene) with chromic acid, two bromotoluic acids, $C^6H^3BrO^2$, are obtained, which form calcium salts of different solubility, the less soluble crystallising in needles containing $(C^6H^3BrO^2)^2Ca + 3H^2O$, the more soluble in smaller needles containing $8H^2O$. The acid separated from the former of these salts melts at 205° – 206° , that from the latter at 185° – 189° ; and by agitating the brominated acid melting at 205° – 206° with sodium-amalgam for two days, the sodium salt of a toluic acid is obtained which, when separated by hydrochloric acid, forms slender needles melting at 90° – 93° , or about 10 degrees lower than orthotoluic acid. This toluic acid, oxidised with chromic acid, yields isophthalic or metaphthalic acid, and consequently consists of metatoluic acid:

Paratoluic or ordinary toluic acid is also produced: α . By distilling potassium sulphotoluate with potassium cyanide, whereby tolyl cyanide is obtained, and saponifying this compound with alcoholic potash:

and

The acid thus obtained melts at 175° – 176° (Morz, *Zeitschr. f. Chem.* [2] iv. 33).— β . Together with one of the other modifications, by heating monobromotoluene (b. p. 178° – 186°) with ethyl chlorocarbonate and sodium-amalgam in a flask fitted with an upright condenser and placed in a sand-bath:

On exhausting the product with ether, distilling off the portion which boils below 180° , decomposing the residue with alcoholic potash, precipitating with hydrochloric acid, recrystallising from water, and distilling, toluic acid is obtained contaminated with a more fusible acid, the whole melting at 153° ; and by repeatedly treating it with a quantity of boiling water less than sufficient for complete solution, the toluic acid is at length obtained pure and melting at 176° (Wurtz, *Compt. rend.* lxxiii. 1298).

Bromotoluic Acids.—*Metabromotoluic acid*, $C^6H^3BrO^2$, produced by oxidising monobromoxylene (from coal-tar xylene) with potassium chromate and dilute sulphuric acid, separates from alcoholic solution as a crystalline powder melting at 205° – 206° , slightly soluble in boiling water and in cold alcohol. Its barium salt, $(C^6H^3BrO^2)^2Ba + 4H^2O$, and the calcium salt, $(C^6H^3BrO^2)^2Ca + 3H^2O$, crystallise in needles; the silver salt, $C^6H^3BrO^2Ag$, is a flocculent precipitate which becomes coloured on exposure to light; the ethylic ether is a fragrant liquid soluble in water, boiling without decomposition at 270° – 275° , and solidifying in the crystalline form at -5° . *Nitrometabromotoluic acid*, $C^6H^2(NO^2)BrO^2$, separates on adding water to the warmed solution of metabromotoluic acid in fuming nitric acid, in the flocculent state, and forms colourless crystals melting at 175° – 176° ; the barium salt, $[C^6H^2(NO^2)BrO^2]^2Ba + 3H^2O$, crystallises in easily soluble needles; the calcium salt, $[C^6H^2(NO^2)BrO^2]^2Ca + 3H^2O$, in warty aggregates. *Metadibromotoluic acid*, $C^6H^2Br^2O^2$, is produced, though very slowly, by oxidising dibromoxylene with chromic acid mixture. It is insoluble in cold water, and crystallises from dilute alcohol in microscopic needles melting at 185° – 186° . The easily soluble barium salt, $(C^6H^2Br^2O^2)Ba + 9H^2O$, forms silky needles; the silver salt, $C^6H^2Br^2O^2Ag$, is an amorphous precipitate insoluble in water (Fittig, Ahrens, a. Mattheides, *Ann. Ch. Pharm.* cxlvii. 15; *Jahresh.* 1867, p. 696).

Nitrotoluic and Amidotoluic acids (Ahrens, *Zeitschr. f. Chem.* [2] v. 102).—Coal-tar xylene, boiling at 138° – 140° , was oxidised with a mixture of 1 vol. nitric acid and 3 vol. water, and yielded a mixture of acids which, after distillation, conversion into calcium salts, and precipitation with hydrochloric acid, melted at 72° – 75° . This product was gently warmed with strong nitric acid, the resulting nitro-acids precipitated by water, and, after washing, saturated with calcium carbonate.

A mixture of calcium salts differing in solubility was thus obtained, which were separated by repeated crystallisation from hot water.—A. The *nitrotoluic acid*, $C^6H^4(NO^2)O^2$, separated from the less soluble calcium salt, crystallised in large monoclinic prisms melting at 190° ; its barium salt in needles containing 4 mol. water; the calcium salt in rhombic prisms with $3H^2O$; the lead salt, obtained as a precipitate, crystallised from hot water in anhydrous needles. *Amidotoluic acid*, $C^6H^4(NH^2)O^2$, formed from the preceding nitro-acid by reduction with tin and hydrochloric acid, crystallises in long, yellow, capillary needles, melting at 164° – 165° . Its barium salt, $[C^6H^4(NH^2)O^2]^2Ba + 3H^2O$, is easily soluble in water; the copper, lead, and silver salts are sparingly soluble, and obtained by precipitation. *Nitroxytoluic acid*, $C^6H^4(NO^2)(OH)O^2$, formed by treating the amido-acid with nitrous acid, forms very long golden-yellow needles, soluble in water, and melting at 187° – 188° . Its barium salt, $[C^6H^4(NO^2)(OH)O^2]^2Ba + 7H^2O$, is easily soluble in water, turns red when dried over sulphuric acid, and deliquesces to a lemon-yellow mass on exposure to the air.

B. The more soluble calcium salts separated from the last mother-liquor obtained as above yield a mixture of two nitrotoluic acids, one crystallising in thick monoclinic prisms melting at 220° , the other in capillary needles melting at 217° – 218° ; the crystalline forms of these two acids are not altered by recrystallisation. They are both insoluble in water, easily soluble in alcohol. The calcium salt of the acid melting at 220° forms well-defined tabular crystals very soluble in water.

Alphatoluic or Phenylacetic Acid. $CH^3\{C^6H^4\}_{COOH}$ —This acid, first obtained by Cannizzaro by boiling benzyl cyanide with potash, afterwards by Möller a. Ströcker from vulpic acid by the action of baryta-water (v. 863), is also produced by heating mandelic (phenyl-glycollic) acid with concentrated hydriodic acid and a small quantity of phosphorus (Crum-Brown, *Proc. Roy. Soc. Edinb.* v. 409):

The *methyl ether* of alphatoluic acid, obtained by treating the acid with alcohol and hydrochloric acid, is a colourless liquid having a faint odour, a sp. gr. of 1.044 at 16° , and boiling without decomposition at 220° . The *ethyl ether*, obtained in like manner, has an unpleasant odour, a sp. gr. of 1.031, and boils at 226° (Radziszewski, *Zeitschr. f. Chem.* [2] v. 358).

Phenylbromacetic or Bromalphatoluic acid, $CHBr\{C^6H^4\}_{COOH}$, is formed by the action of hydrobromic acid on mandelic acid:

A solution of mandelic acid in fuming hydrobromic acid yields phenyl-bromacetic acid, gradually at ordinary temperatures, more quickly when heated, in oily drops which gradually crystallise. By recrystallisation from carbon bisulphide, it is obtained in yellow prisms melting at 382° . By sodium-amalgam and water it is reduced to alphatoluic acid. Potassium hydrate added to its alcoholic solution quickly converts it into phenyl-ethyl-glycollic acid:

The resulting solution filtered from potassium bromide, slightly acidulated with hydrochloric acid, then evaporated over the water-bath, and mixed with lukewarm water, leaves a yellowish oil, consisting of phenyl-ethyl-glycollic acid, which may be converted into a barium salt and separated therefrom by hydrochloric acid, in the form of a transparent, uncrystallisable, glutinous mass resembling bird-lime. Its salts are also mostly amorphous. The *barium salt* is very soluble in water, and remains as a gummy mass on evaporation in a vacuum. The *lead salt* is sparingly soluble, and becomes crystalline on standing. The *silver salt* is a white pulverulent precipitate (Glaser a. Radziszewski, *Zeitschr. f. Chem.* [2] iv. 140).

Phenylethylchloracetic or Chloralphatoluic acid, $CHCl\{C^6H^4\}_{CO^2H}$, is prepared by heating mandelic acid with excess of fuming hydrochloric acid to 146° in sealed tubes for two or three hours, dissolving the resulting oil in sodium carbonate, decolorising with animal charcoal, and precipitating with hydrochloric acid. It then separates as a colourless oil, which gradually solidifies, and the mother-liquor yields

the same acid in white rhomboidal tables. It is soluble in alcohol, ether, carbon bisulphide, and chloroform, slightly soluble in water, melts at 78° , and solidifies in prismatic needles. Its salts crystallise with difficulty. In dilute alcoholic solution it is easily converted by sodium-amalgam into alphetoluic acid. By boiling with excess of potash it is converted into an acid soluble in water, the barium salt of which has the form and composition of the mandelate (Radziszewski, *ibid.* v. 356).

Phenyldichloroacetic acid, $\text{CCl}_2\left\{\begin{smallmatrix} \text{C}^6\text{H}^5 \\ \text{CO}_2\text{H} \end{smallmatrix}\right.$, is obtained either by the action of dry chlorine on the monochlorinated acid in sunshine, or by passing chlorine gas through the same acid in a U-tube immersed in boiling water, and purified by conversion into sodium salt and precipitation with hydrochloric acid. It then separates as an amber-coloured oil which gradually solidifies, and the remaining liquid becomes filled with square tables united in laminar groups. It melts at 69° and solidifies in crystalline scales; is slightly soluble in water, and crystallises therefrom in transparent square tables, from ether in small concentrically grouped needles. Its salts crystallise better than those of the monochlorinated acid. By dry distillation, it gives off chlorine, hydrochloric acid, and a yellow oil, leaving a carbonaceous residue. By boiling with excess of potash, it is converted into an acid easily soluble in water. When it is boiled with potash till the solution no longer gives a precipitate with sulphuric acid, and then boiled with sulphuric acid and potassium dichromate, it gives off vapours smelling like bitter almond oil, and is finally converted into benzoic acid (Radziszewski, *loc. cit.*).

Parabromophenylacetic acid is formed by the action of bromine on a toluic acid. It crystallises in prisms melting at 76° ; its barium and calcium salts form nodular groups of crystals easily soluble in water and alcohol. By oxidation with chromic acid mixture, it is converted into parabromobenzoic acid melting at 251° , together with another brominated acid which melts at 99° . Nitric acid converts it into parabromonitrophenylacetic acid, which crystallises in prisms. When bromine acts on a toluic acid at 150° , the chief product is phenylbromacetic acid, which by boiling with soda-ley is converted into mandelic acid (Radziszewski).

Paranitrophenylacetic acid, $\text{CH}(\text{NO}_2)\left\{\begin{smallmatrix} \text{C}^6\text{H}^5 \\ \text{CO}_2\text{H} \end{smallmatrix}\right.$, obtained by the action of fuming nitric acid on a toluic acid at ordinary temperatures, crystallises from alcohol in colourless prisms melting at 114° . Its sodium salt, $\text{C}^6\text{H}^5(\text{NO}_2)\text{O}^2\text{Na} + 2\text{H}_2\text{O}$, crystallises from alcohol in square tables. The acid saturated with ammonia forms a yellowish precipitate with silver salts, green with copper salts, white with mercurous and mercuric salts. The *ethylic ether* obtained by nitration of ethylic phenylacetate, crystallises from alcohol in rhombic tables melting at 64° . The nitro-acid is converted by oxidation with chromic acid mixture into paranitrobenzoic acid, melting at 230° .

Para-amidophenylacetic acid, $\text{CH}(\text{NH}_2)\left\{\begin{smallmatrix} \text{C}^6\text{H}^5 \\ \text{CO}_2\text{H} \end{smallmatrix}\right.$, is obtained, in combination with stannous chloride, by treating the nitro-acid with tin and hydrochloric acid. When separated therefrom it crystallises in nacreous laminae, easily decomposed by heat or by contact with moist air, insoluble in cold water, moderately soluble in warm water and in alcohol. Its *hydrochloride* forms long colourless needles, not volatile without decomposition; the *neutral sulphate* crystallises easily in six-sided tables. The *silver salt* is a white unstable precipitate; the *copper salt* is green, and quite insoluble in water.

When the mononitrated acid is reduced by ammonium sulphhydrate, and the amidated acid is precipitated by acetic acid, a yellowish liquid remains, from which hydrochloric acid throws down para-azophenylacetic acid. This acid is insoluble in cold water, and crystallises from hot water in very long nacreous straw-coloured needles melting at 138° .

Dinitrophenylacetic acid is formed by treating the paranitro-acid with a mixture of nitric and sulphuric acid. It crystallises from water in thin needles melting at 160° , and easily forms ethers. Another nitro-acid is formed at the same time in small quantity (Radziszewski).

TOLUIDINE or **AMIDOTOLUENE**. $\text{C}^6\text{H}^5\text{N} = \text{C}^6\text{H}^4(\text{NH}_2) = \text{C}^6\text{H}^3\left\{\begin{smallmatrix} \text{CH}_3 \\ \text{NH}_2 \end{smallmatrix}\right.$ —

This base exhibits the three modifications, ortho-, meta-, and para-. The crystallised base obtained by Hofmann & Muspratt in 1840, by reduction of nitrotoluene, appears to be paratoluidine; a liquid modification lately discovered by Rosenstiehl in commercial toluidine, and named *pseudo-toluidine*, is most probably the ortho-modification; and metatoluidine may also be obtained from crude commercial toluidine (p. 1103).

Ordinary crystallised toluidine is obtained by reduction of solid nitrotoluene; it melts at 46° and boils at 200° (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] v. 523). Pseudotoluidine, which is liquid at ordinary temperatures, is obtained by reduction of liquid nitrotoluene (Beilstein a. Kuhlberg), also from crystallised bromotoluene, by converting that compound into bromonitrobenzene, reducing the latter with tin and hydrochloric acid, whereby it is converted into bromotoluidine, and debrominating this base with sodium-amalgam (Hübner a. Wallach, *Zeitschr.* v. 139; Körner, *ibid.* 319). The same modification is obtained by heating nitro-acetoluidine, $C^6H^4(NO_2).NH(C^2H^5O)$, with alcoholic potash, whereby it is converted into a nitrotoluidine, $C^6H^4(NO_2)NH^2$, which crystallises in rhombic prisms melting at 114° ; treating the nitrate of this base with nitrous acid, which converts it into orthonitrotoluene, $C^6H^4(NO_2)$ (liquid at ordinary, solidifying at low temperatures, boiling at 227° , and converted by oxidation with chromic acid into orthonitrobenzoic acid); and lastly, reducing this nitrobenzene with tin and hydrochloric acid, and distilling the product with lime. The toluidine thus obtained, which is orthotoluidine, is a transparent colourless liquid, becoming rose-coloured on exposure to the air, remaining liquid at -13° , having a sp. gr. of 0.998 at 25° , and boiling constantly at 197° (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] vi. 102). The pseudotoluidines obtained by Körner, and by Hübner a. Wallach, exhibit the same physical characters (boiling point 196° – 198°); so likewise does the pseudotoluidine which Rosenstiehl obtained from commercial toluidine from Coupiér's aniline works. This commercial toluidine is liquid, boils at 198° , and when cooled to 0° yields ordinary crystallised toluidine, the remaining liquid still boiling at 198° . On converting this liquid toluidine into oxalate, and exhausting with anhydrous ether, ordinary toluidine oxalate remains undissolved, and oxalate of pseudotoluidine dissolves. This salt decomposed with soda-ley yields pseudotoluidine boiling at 198° , and remaining fluid at -20° (Rosenstiehl, *Bull. Soc. Chim.* [2] x. 192; *Jahresb.* 1868, p. 744).

When pseudotoluidine nitrate is treated with nitrous acid, the resulting diazotoluene nitrate converted into sulphate by treatment with sulphuric acid, and this sulphate treated with hydriodic acid, an iodotoluene is obtained which is converted by oxidation with chromic acid mixture into ortho-iodobenzoic acid, and by fusion with potash into oxybenzoic acid. All these compounds, therefore, and the pseudotoluidine from which they are derived, belong to the ortho-series. The same series of reactions performed upon ordinary crystallised toluidine show that it has the constitution of paratoluidine (Körner, *ibid.* 636).

Metatoluidine may be obtained from crude commercial toluidine, containing both the para- and the meta-compounds, by heating it with a slight excess of glacial acetic acid for sixteen hours, whereby the greater part is converted into crystallised meta-tolylacetamide, and distilling this product with alcoholic potash. Metatoluidine then passes over with the steam, and crystallises in large octohedrons melting at 57° , and boiling with complete decomposition at 240° ; it dissolves easily in alcohol, sparingly in water (Wroblevsky, *Zeitschr. f. Chem.* [2] vii. 185; *Chem. Soc. J.* [2] ix. 563).

Coupiér's liquid toluidine contains about 36 p. c. of pseudotoluidine; commercial aniline frequently contains more than 20 p. c. of it. Pseudotoluidine does not yield any red compound when heated with arsenic acid, but a mixture of it with crystallised toluidine yields a large quantity of red colouring matter containing at least 50 p. c. rosaniline salt; during the reaction a large quantity of aniline distils over. A mixture of pseudotoluidine with aniline, treated with arsenic acid, yields a large quantity of a red colouring matter resembling fuchsine, but distinguished from rosaniline salts by the solubility of its base in ether, and the greater solubility of its chloride in water. Pseudotoluidine salts mixed with cupric chloride dye cotton-wool a fine black with a tinge of violet (Rosenstiehl, *loc. cit.*).

Bromotoluidines. Monobromotoluidine, $C^6H^4Br.N = C^6H^4Br.\{CH^3\}_{NH^2}$ is produced: 1. From bromotoluene, $C^6H^4Br.CH^3$ (b. p. 179° – 181°), by conversion into nitrobromotoluene (b. p. 255° – 256°), reduction of this compound with tin and hydrochloric acid, and distillation of the product with caustic soda. The bromotoluidine thus obtained is a limpid oil insoluble in water, turning red-brown on exposure to light or by prolonged boiling, crystallising when moderately cooled in slender needles. It boils at 253° – 257° , and decomposes to a slight extent when distilled. It forms salts which crystallise easily from acetic acid, the sulphate, nitrate, and hydrochloride in laminae, the oxalate and tartrate in needles. By prolonged agitation with sodium-amalgam, it is debrominated and converted into orthotoluidine, boiling at 196° – 198° , and remaining liquid at -21° (Hübner a. Wallach, *Zeitschr. f. Chem.* [2] v. 22, 530).

Wroblevsky (*ibid.* vi. 165) has obtained two isomeric bromonitrotoluenes, and corresponding modifications of bromotoluidine. Crystallised (para-) bromotoluene was nitrated, the solution precipitated by water; the oily product, after washing and drying, was exposed to a freezing mixture; and the solidified mass subjected to strong pressure at a winter temperature. The solid product which remained did not melt at the ordinary temperature of a room. On boiling the press-cake with water, an oily product passed over, which did not solidify at -20° . The solid (α) bromonitrotoluene recrystallised from alcohol forms long needles, melts at 43° , and boils without decomposition at 256° – 257° . The liquid (β) bromonitrotoluene remains liquid at -20° , has a sp. gr. of 1.631 at 18° , and boils at 255° – 256° . In the solid modification the nitro-group appears to occupy the *meta*-place.

α Bromotoluidine prepared from the solid nitro-compound by the action of tin and hydrochloric acid is liquid, and solidifies at -2° . β Bromotoluidine prepared in like manner from the liquid nitro-compound is solid, crystallises in prisms, and melts at 67° . The nitrate of the α base forms beautiful nacreous crystals, soluble in 120.9 pts. water at 11.5° ; the β nitrate forms prismatic crystals, soluble in 217.4 pts. water at 11.5° .

2. From acetoluidine, $C^7H^7:NH(C^2H^3O)$ (v. 871). This compound treated under water with 2 at. bromine, and gently warmed, is converted into bromacetoluidine, $C^7H^7Br:NH(C^2H^3O)$, which crystallises in needles melting at 117° , and when boiled with alcoholic potash is resolved into acetic acid and bromotoluidine. The base thus obtained boils at 220° , is insoluble in water, easily soluble in alcohol, and has a specific gravity of 1.510 at 20° . The nitrate crystallises in very fine large yellow laminae, the hydrochloride in white nacreous prisms, the acid oxalate and acid sulphate in needles (Wroblevsky, *ibid.* v. 279).

3. Together with dibromotoluidine, by the direct action of bromine on toluidine. When 1 mol. bromine is passed, by means of a current of air, into aqueous toluidine hydrochloride, or into the alcoholic solution of free toluidine, a copious precipitate of dibromotoluidine is obtained, together with a small quantity of monobromotoluidine. The alcoholic solution is mixed with water, the precipitated dibromotoluidine separated by filtration, the acid filtrate evaporated to dryness over the water-bath as long as acid vapours continue to escape, the residue then dissolved in cold water, and the filtered solution mixed with ammonia, which throws down only monobromotoluidine. To purify this base it is converted into a crystallised salt, and this salt is decomposed by distillation with potash. The bromotoluidine thus obtained forms a hydrochloride and nitrate agreeing exactly with those of the bromotoluidine prepared from acetoluidine. The nitrate is converted by nitrous acid into a diazobromotoluene, the sulphate of which decomposed by alcohol yields orthobromotoluene, C^7H^7Br , convertible by oxidation with chromic acid into orthobromobenzoic acid (Wroblevsky, *ibid.* v. 460).

Dibromotoluidine, $C^7H^7Br_2(NH^2).CH^3$, crystallises in long white silky needles melting at 73° , insoluble in water, but soluble in alcohol and ether. It does not unite with acids, is scarcely acted upon by bromine, but is strongly attacked by fuming nitric acid, apparently yielding products of oxidation (Wroblevsky).

On bromotoluidines, see further Wroblevsky (*Zeitschr. f. Chem.* [2] vii. 135, 240; *Chem. Soc. J.* [2] ix. 564, 713).

Chlorotoluidine. $C^7H^7ClN = C^6H^5Cl \left\{ \begin{smallmatrix} CH^3 \\ NH^2 \end{smallmatrix} \right.$ —This base has been obtained in three modifications, two liquid at ordinary temperatures, the third solid.

1. Acetoluidine suspended in water and treated with chlorine gas till the vessel shows an increase of weight corresponding to 2 at. chlorine, is converted into chloracetoluidine, $C^7H^7Cl:NH(C^2H^3O)$, which crystallises in large red laminar crystals, melting at 99° , and resolved by boiling with alcoholic potash into acetic acid and chlorotoluidine. The chlorinated base thus obtained is a colourless liquid smelling like toluidine; it boils without decomposition at 222° , has a sp. gr. of 1.151 at 20° , dissolves easily in alcohol, but is nearly insoluble in water. Its salts crystallise very beautifully, the nitrate and hydrochloride in prisms, the latter subliming at 100° , the acid sulphate in prisms, the acid oxalate in long white needles (Wroblevsky, *Zeitschr. f. Chem.* [2] v. 322).

2. Parachloronitrotoluene, $C^7H^7Cl(NO^2)$, obtained by direct nitration of parachlorotoluene, is converted by tin and hydrochloric acid into a double salt $2(C^7H^7ClNH^2.HCl).SnCl_2$, from which the tin may be separated by hydrogen sulphide, leaving parachlorotoluidine hydrochloride, $C^7H^7ClNH^2.HCl$, and from this salt the (para-) chlorotoluidine may be separated by distillation with caustic soda. The chlorinated base thus obtained is a colourless, oily, strongly refracting liquid, smelling like ordinary toluidine, having a sp. gr. of 1.175 at 18° , and boiling at 236° (i.e. 14° higher than the preceding); it becomes coloured in contact with the air. Its hydrochloride forms very light nacreous laminae, which may be purified by sublimation; the nitrate

crystallises in thin translucent perfectly white laminae; the sulphate is very soluble in water (Henry a. Radziszewski, *ibid.* 542).

According to a later statement by the same authors (*ibid.* vi. 157), the chlorotoluidine obtained as above crystallises in needles, melts at 85°, and boils at 243°.

Wroblevsky (*ibid.* 683), by treating pure chlorotoluene with nitric acid of sp. gr. 1.475, and subjecting the product to fractional distillation, obtained two nitrochlorotoluenes, one (α) boiling at 243°, the other (β) at 253°, both of which remained perfectly fluid at -13°. Both of these were converted into chlorotoluidines by reduction with tin and hydrochloric acid.

α *Chlorotoluidine* from a nitrochlorotoluene is a liquid not solidifying at -14°. It is colourless, but turns brown on exposure to the air, and has a faint odour like that of toluidine. Sp. gr. 1.1855 at 20°. Boiling point 238°. Insoluble in water, easily soluble in alcohol. Its nitrate and hydrochloride crystallise in prisms, the latter subliming like sal-ammoniac.

β *Chlorotoluidine* is a liquid when first separated, but solidifies on standing, or more quickly when cooled. When freed from the adhering liquid modification by pressure, distillation, and crystallisation from alcohol, it forms large colourless nacreous laminae melting at 83° and boiling at 241°. It is nearly insoluble in water, easily soluble in alcohol, and has a faint odour. Its salts crystallise remarkably well, the hydrochloride in colourless nacreous laminae with pointed ends, subliming like sal-ammoniac, but much less soluble in water than the α salt; the nitrate in large shining tables melting with decomposition at 169°.

The two chlorotoluidines obtained by Wroblevsky are probably identical with those described by Henry a. Radziszewski; the second has also been obtained by Beilstein a. Kuhlberg (*ibid.* 281).

Nitrotoluidine, $C^6H^4(NO^2)(NH^2) = C^6H^4(NO^2)\left\{ \begin{smallmatrix} CH^3 \\ NH^2 \end{smallmatrix} \right\}$, obtained by reduction of dinitrotoluene, forms broad yellow shining needles melting at 77.5°, easily soluble in hot water, very slightly in cold water. The *nitrate* forms small yellow anhydrous laminae melting with decomposition at 185°. The *hydrochloride* forms tufts of yellow needles, or, slowly crystallised, long yellow slender needles; melts with decomposition at 220°; is moderately soluble in water, especially at the boiling heat. The *sulphate*, $[C^6H^4(NO^2)(NH^2)]^2 \cdot H_2SO^4 + 2H^2O$, pale rose-coloured needles arranged in stellate groups. The nitrate is converted by nitrous acid into *nitrate of diaconitrotoluene* $C^6H^4(NO^2)N^2$, NO^2 (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] v. 280).

Vinyl-toluidine, $C^6H^4N = C^6H^3(C^2H^3) \cdot NH^2$ (Wurtz, *Compt. rend.* lxxiii. 1504; *Zeitschr. f. Chem.* [2] v. 482), is produced by heating 1 mol. toluidine with 3 mol. glycolic chlorhydrin to 220°-225° for several hours. A thick brown liquid is then formed, which dissolves only partially in water, with separation of a black flocculent or resinous mass. On agitating the whole with ether, a considerable quantity of vinyl-toluidine is dissolved, part of which sometimes separates in the form of a powder which may be dissolved in ether, or better in benzol. The ethereal solution when left to evaporate yields coloured crystals of the same base, which may be purified by washing with a little ether, and recrystallisation from benzol. It then forms perfectly colourless prisms melting at 189°-191° and resolidifying at 183°; is quite insoluble in water; dissolves in moderately concentrated sulphuric and hydrochloric acid, but is reprecipitated from these solutions by water in its original state. It is therefore a very weak base, but nevertheless forms a yellow platinochloride, $2(C^6H^4N \cdot HCl) \cdot PtCl^4$, when platonic chloride is added to its solution in hydrochloric acid. Vinyl-toluidine is likewise formed when toluidine is heated to 195°-205° with an equal weight of ethylene bromide, the brominated base $C^6H^4 \cdot NH(C^2H^3Br)$, which is the normal product of the reaction, being resolved into hydrobromic acid and vinyl-toluidine.

The coloured aqueous mother-liquor, from which the vinyl-toluidine has been extracted by ether or benzol, contains the hydrochlorides of two bases, $C^6H^4(C^2H^3)_2N$ and $C^6H^3(C^2H^3OH)(C^2H^3)N$, in variable proportion; the latter when predominant imparts to the liquid a deep colour and very distinct green fluorescence. These bases may be separated by fractional precipitation with platonic chloride, the platinochloride of the di-vinyl base separating out first. The *hydrochloride* of this base, $C^6H^4N \cdot HCl$, separated from the platinochloride by hydrogen sulphide, crystallises with 1 mol. water, which is given off at 100°. Ammonia added to the solution throws down colourless oily drops. In an atmosphere of bromine the solution of the hydrochloride takes up 6 at. bromine, forming a red liquid, which evaporates over quick lime to a ruby-coloured crystalline mass.

Sup.

The *platinochloride* of the other base, decomposed with hydrogen sulphide, yields a yellow solution with splendid green fluorescence, which when evaporated in a vacuum leaves a coloured crystallised mass. These crystals dissolve in alcohol, and the solution covered with a layer of ether yields the *hydrochloride*, $C^{11}H^{12}NO \cdot HCl$, in brownish-yellow nodules. The concentrated aqueous solution of this salt is brownish-yellow, and possesses great colouring power; when diluted it turns yellow; and when very greatly diluted reflects light with a beautiful green colour. The dry *hydrochloride* exposed to an atmosphere saturated with bromine deliquesces to a red liquid, which solidifies over quick lime to an orange-red crystalline mass containing about 4 at. bromine to 1 mol. of the hydrochloride. The solution of the hydrochloride treated with a large excess of hydriodic acid and left to evaporate, yields crystals of the *hydriodide*, $C^{11}H^{12}NO \cdot HI$, which when recrystallised from water forms golden-yellow laminae; its solution is not fluorescent. With silver nitrate, this salt yields a soluble strongly fluorescent nitrate.

The two bases $C^{11}H^{11}N$ and $C^{11}H^{12}NO$ are not true derivatives of toluidine, inasmuch as they contain, not the radicle tolyl, C^7H^7 , but toluenyl, C^7H^8 . The group C^7H^7 in fact gives up H^2 , and this hydrogen converts part of the glycolic chlorhydrin into ethyl chloride and water: $C^7H^8ClO + H^2 = C^7H^8Cl + H^2O$. The crude coloured product of the reaction contains indeed ethyl chloride, together with ethylene chloride, the latter formed according to the equation, $C^7H^8ClO + HCl = H^2O + C^7H^8Cl^2$. The hydrochloric acid required for this last reaction is supplied by the reaction of 3 mol. glycolic chlorhydrin on a single molecule of toluidine (Wurtz).

TOLUQUINONES (Graebe a. Borgmann, *Zeitschr. f. Chem.* [2] iv. 118;—Borgmann, *ibid.* vi. 122).—The di- and tri-chlorinated derivatives of the quinone of toluene are obtained by the action of potassium chlorate on cresol, just as the chlorinated quinones of the benzene series are produced from phenol. These compounds are represented by the formulae:

The dichlorinated compound has not been obtained pure. *Trichlorotoluquinone*, purified by repeated crystallisation from alcohol, forms yellow laminar crystals sparingly soluble in cold, more easily in boiling alcohol, easily soluble in ether and in chloroform, almost insoluble in boiling water. It sublimes with aqueous vapours, decomposes before it melts, and forms with soda-ley a red-brown solution which after a while deposits red crystals.

Trichlorotoluhydroquinone, $C^7H^8Cl^3O^2 = C^6[CH^3(OH)^2Cl^3]$, is obtained by heating tritolchloroquinone with aqueous sulphurous acid, and recrystallising the resulting crystals from large quantities of boiling water or dilute alcohol, with addition of a little sulphurous acid. It forms colourless inodorous needles, dissolves easily in alcohol, very sparingly in water, melts at 212° , sublimes without decomposition, dissolves with red colour in ammonia or caustic soda, and in aqueous solution forms with lead salts a precipitate soluble in acetic acid. When moist it turns green on exposure to the air. Oxidising agents convert it into trichlorotoluquinone.

Diacetyl-trichlorotoluhydroquinone, $C^7H^3(C^2H^3O)^2Cl^3O^2$, is formed when trichlorotoluhydroquinone is heated to 100° for some time with excess of acetyl chloride. The resulting crystals may be purified by washing with water and dilute soda-ley and sublimation. It melts at 114° , sublimes in prismatic needles, dissolves sparingly in water, easily in alcohol and ether, is not attacked by soda-ley even when heated, but fuming nitric acid at the boiling heat slowly converts it into trichlorotoluquinone.

Diethyl-trichlorotoluhydroquinone, $C^7H^3(C^2H^5)^2Cl^3O^2$, is produced by heating trichlorotoluhydroquinone (1 mol.) to 140° – 150° for four hours with potassium hydrate (2 mol.), ethyl iodide (rather more than 2 mol.), and a little alcohol, and purified by digesting the resulting crystals on the water-bath with strong soda-ley, washing with water, and sublimation. It melts at 107° , sublimes in slender needles, dissolves sparingly in water, easily in alcohol and ether, is not attacked by potash-ley.

Monochlorotoluhydro-bisulphoquinonic Acid.—The potassium salt of this acid, $C^7H^4ClO^4(SO^2K)^2$, is formed by dissolving trichlorotoluquinone at a gentle heat in concentrated aqueous potassium bisulphite, and separates after some time as a granular precipitate, which by recrystallisation from hot water is converted into

white shining laminae. It is insoluble in alcohol, slightly soluble in cold, moderately soluble in hot water, not precipitated by barium chloride. With neutral lead acetate it forms a white, with the basic acetate a yellow precipitate, both soluble in acetic acid. It dissolves in soda-ley, forming a yellow solution (Borgmann).

TOLURIC ACID. $C^6H^11NO^2$.—According to Schultzen a. Naunyn (*Zeitschr. f. Chem.*, [2] iv. 29), this acid is found in the urine after xylene has been swallowed; the acid which they obtained did not however agree in its properties with that described by Kraut (v. 868), the acid itself and the barium salt being uncrystallisable. The zinc salt, $(C^6H^10NO^2)Zn + 4H^2O$, crystallised in white silvery laminae; the copper salt, $(C^6H^10NO^2)Cu + 6H^2O$, in groups of blue-green needles.

TOLUYLENE or STILBENE. C^8H^{12} .—This hydrocarbon, discovered by Laurent (v. 431), is produced, together with tolalyl sulphide and thionessal, by the dry distillation of benzyl sulphide, benzyldisulphide, and sulphobenzide (v. 869, and Supplement, p. 1087).—2. Together with toluene, by heating bromotoluene with sodium:

(Fittig, *Ann. Ch. Pharm.* cxxxix. 178).

3. By the action of sodium on benzylene chloride at the boiling heat: $2C^7H^6Cl^2 + 2Na^2 = 4NaCl + C^8H^{12}$ (Limpricht, *ibid.* 303).—4. By heating bitter almond oil with sodium:

On distilling the product, the portion which goes over at 265° consists almost wholly of toluylene (C. Gr. Williams, *Chem. News*, xv. 214).

Toluylene crystallises in nacreous plates, as observed by Laurent (v. 431). It melts at 119.5° (Limpricht), at 120° (Fittig; Williams). Vapour-density = 6.024 (Williams); calc. for $C^8H^{12} = 6.228$.

Toluylene heated for eight hours to 140° – 150° , with concentrated *hydriodic acid*, is converted, by addition of hydrogen, into dibenzyl, $C^{10}H^{14}$, which separates from alcohol in crystals melting at 48° – 50° . By similar treatment with hydrobromic acid, toluylene suffers no alteration. In *fuming sulphuric acid* it dissolves, with formation of a non-crystallisable sulpho-acid, whose barium salt, $C^{10}H^{14}BaS^2O^6$, is separated from aqueous solution by alcohol, as a yellowish amorphous precipitate.

With *nitric acid* toluylene forms resinous, difficultly crystallisable nitro-products, one of which separated from the ethereal solution, on addition of alcohol, in yellow nodules melting at 180° , and having approximately the composition $C^8H^{10}(NO^2)^2$. This compound was reduced by tin and hydrochloric acid to an unstable, insoluble base crystallising in needles and represented approximately by the formula $C^8H^{10}(NH^2)^2$ (Märcker, *Ann. Ch. Pharm.* cxl. 86).

Toluylene Bromide. $C^8H^{12}Br^2$, separates almost completely on mixing a solution of toluylene in ether or carbon bisulphide with bromine, whilst substitution-products (e.g. $C^8H^{11}Br$) remain in solution. The bromide, after washing with ether, and boiling with strong alcohol, consists of small silky needles, slightly soluble in boiling absolute alcohol, rather more soluble in ether and carbon bisulphide, moderately soluble in hot xylene, melting at 230° – 235° , and resolved by distillation at a higher temperature into bromine, hydrobromic acid, toluylene, and monobromotoluylene, $C^8H^{11}Br$. Heated to 130° for some hours with *alcoholic potash*, it is converted into monobromotoluylene, which latter is further partially converted at the same time, or completely by 10 to 12 hours' heating to 130° into toluene, C^7H^{10} (p. 1099). Toluylene bromide heated with *ammonia* to 150° for eight hours, or with aniline to 130° for twelve hours, is reconverted into toluylene. Heated with *water* to 150° , it yields, besides hydrobromic acid and toluylene, a body, $C^8H^{10}O^2$ (probably benzole), which crystallises in four-sided needles, melts at 95° , and volatilises without decomposition. Toluylene bromide heated with dry *silver oxide* and xylene to 140° , or with alcohol to 150° , yields, together with toluylene, an oily body having the composition $C^8H^{12}O^2$. By *hydriodic acid* toluylene bromide is converted into dibenzyl, by alcohol and sodium-amalgam into toluylene and dibenzyl (Limpricht a. Schwancert, *Ann. Ch. Pharm.* cxlv. 330).

Monobromotoluylene, $C^8H^{11}Br$, is a light yellow oily liquid, soluble in alcohol and ether, and partially decomposed by distillation. *Bromotoluylene bromide*, $C^8H^{11}Br^2 = C^8H^{11}Br.Br^2$, formed on mixing the ethereal solution of bromotoluene with bromine,

* This compound was likewise obtained by Märcker (*Jahresb.* 1866, p. 600), who however regarded it as $C^8H^{10}Br^2$.

crystallises in white needles, slightly soluble in cold, easily in hot alcohol and in ether, melting at 100° , and resolved by distillation into bromine, hydrobromic acid, toluene, C^1H^{10} , and toluene bromide, $C^1H^{10}Br^2$:

and

The alcoholic solution of bromotoluene bromide mixed with silver nitrate immediately yields silver bromide; heated with alcoholic soda-solution, it yields toluene, and with water at 140° , toluene bromide.

Toluylene Acetate, $C^1H^{12}(C^2H^3O^2)^2$, is formed by heating 1 mol. toluylene bromide and 2 mol. silver acetate for four hours to 130° with glacial acetic acid, as an oil precipitable by water, and solidifying to a crystalline mass. From xylene mixed with a little alcohol, it crystallises in warty crusts melting at 120° . The oxalate is formed as a resinous uncrystallisable mass by heating toluylene bromide dissolved in xylene with silver oxalate.

Toluylene Alcohol, $C^1H^{14}O^2 = C^1H^{12}(HO)^2$, identical with hydrobenzoin (p. 332), is obtained by heating toluylene acetate with alcoholic potash or the oxalate with alcoholic ammonia. It separates from alcohol or ether by spontaneous evaporation in rather large solid crystals, which soften at 112° , and melt completely at 122° . Nitric acid converts it into benzoin, $C^1H^{14}O^3$.

Toluylenic Ether or Toluylene Oxide, $C^1H^{12}O$, probably identical with deoxybenzoin (p. 332), was once obtained by heating toluylene acetate to 120° with alcoholic potash, and crystallised from alcohol in large very flat needles melting at 58° (Limpricht a. Schwanert).

TOLYL. $C^7O = C^6H^4(CH^3)$.—A radicle isomeric with benzyl, $CH^2(C^6H^3)$, the former being methylated phenyl, the latter phenylated methyl. The difference of structure of these radicles in the free state may be represented by the following formulæ:

TOLYL ACETATE appears to be formed, as a liquid having an agreeable odour, by heating monochloroxylylene with silver acetate (Lauth a. Grimaux, *Bull. Soc. Chim.* [2] vii. 233).

TOLYL ALDEHYDE, $C^6H^5O = C^6H^4 \cdot CHO = C^6H^4 \left\{ \begin{array}{l} CH^3 \\ CHO \end{array} \right.$, is produced, by heating monochloroxylylene, $C^6H^4 \left\{ \begin{array}{l} CH^3 \\ CH^2Cl \end{array} \right.$ with $\frac{1}{2}$ mol. lead nitrate and 6 or 7 pts. of water, as a liquid smelling like bitter almond oil and cinnamon oil, boiling at 200° , and capable of uniting with acid sodium sulphite.

TOLYL-FORMAMIDE. *Pseudotolyl formamide*, $N(CHO \cdot C^6H^4 \cdot H)$, obtained by dry distillation of pseudotoluidine formate, crystallises in nacreous laminae, slightly soluble in water, easily in a solution of pseudotoluidine formate. It melts at 50° , solidifies again at 30° , and is resolved by dry distillation, or by heating with phosphoric anhydride, fused calcium chloride, or fuming hydriodic acid, into carbon monoxide and pseudotoluidine (Rosenstichl, *Zeitschr. f. Chem.* [2] v. 189).

TOPAZ. Analyses of this mineral from various localities, by Rammelsberg (*Berl. Akad. Ber.* 1865, p. 264; *J. pr. Chem.* xcvi. 7; *Jahresb.* 1865, p. 894), confirm the formula $Al^2Fe \cdot SiF^4 + 5(Al^2O^3 \cdot SiO^2)$ previously assigned to it by the same chemist (v. 875). See also Städelor (*J. pr. Chem.* xcix. 65; *Jahresb.* 1866, p. 942).

TORMENTIL (Rembold, *Ann. Ch. Pharm.* cxlv. 5).—The root of *Potentilla Tormentilla* contains, together with a little ellagic acid, a large quantity of quinovic acid, and a tannin which is resolved by acids into tormentil-red and sugar. When the aqueous decoction of the root is precipitated with neutral lead acetate, the washed precipitate decomposed under warm water with hydrogen sulphide, and the somewhat concentrated liquid mixed with neutral and basic lead acetate successively, two precipitates are obtained, the first of which, *a*, is pale red, the second, *b*, nearly white. These precipitates, when well washed and again decomposed, yield corresponding liquids, A and B. The red-brown liquid, A (which does not give up to ether either gallic acid or any other crystalline body), deposits, when boiled for several hours with dilute sulphuric acid, red-brown, amorphous tormentil-red, together with a little quinovic acid. The liquid filtered therefrom contains a sugar which, after purification, forms a honey-yellow syrup having the composition $CH^{12}O^4$.

When the extract-like evaporation-residue of the liquid A is boiled for some hours with strong potash-ley, and the resulting mass is supersaturated with sulphuric acid, ether extracts from it ellagic acid (slightly soluble in water), and a crystalline body precipitable by neutral lead acetate (perhaps impure protocathecuic acid), turned blue and afterwards green by ferric chloride.

The tormentil-red obtained as above is separated from the quinovic acid by treatment with baryta-water; the brown insoluble compound separated by filtration from the dissolved barium quinovate is decomposed while yet moist by hydrochloric acid; and the washed residue is dissolved in dilute ammonia and again decomposed with hydrochloric acid. Tormentil-red is thus obtained as a red-brown, amorphous precipitate resembling phlobaphene in its chemical relations. It has the same composition as ratanhia-red or chestnut-red, and is probably identical therewith, inasmuch as it is resolved by oxidation with potassium hydrate into protocathecuic acid and phloroglucin.

The liquid B, obtained from the lead-precipitate *b*, is nearly colourless, and when carefully evaporated leaves yellow-reddish amorphous tormentil tannin, having, when dried at 120°, the composition $C^{22}H^{20}O^{11}$. When boiled with dilute sulphuric acid, it is converted, like chestnut-tannin, without sensible formation of sugar, into tormentil-red, which has nearly the same composition. Tormentil-tannin precipitates solution of gelatin, and gives with ferric chloride a blue-green coloration, changing to violet-red on addition of sodium carbonate. The sugar formed by boiling the liquid A with sulphuric acid appears to be produced chiefly from the quinovin, which is resolvable into sugar and quinovic acid.

The quinovic acid, $C^{21}H^{18}O^8$, is obtained in rather large quantity, by twice boiling the tormentil root with thin milk of lime, acidulating the filtrate, boiling the washed precipitate with baryta-water, and again precipitating the filtered solution with hydrochloric acid. The washed precipitate is dissolved in a large quantity of hot alcohol, the reddish solution decolorised with animal charcoal, and part of the alcohol is distilled off; the pure quinovic acid then separates as a colourless, sandy, crystalline powder.

TOURMALINE (Rammelsberg, *Deut. chem. Ges.* 1869, p. 349; *Zeitschr. f. Chem.* [2] v. 568).—The tourmalines form an isomorphous group containing the following elements:

Univalent: H, K, Na, Li — F
 Bivalent: Mg, Ca, Mn, Fe — O
 Quadrivalent: Si
 Tri- and Sexvalent: B and Al.*

Each individual tourmaline is a molecularly isomorphous mixture of analogously constituted primary compounds. There are tourmalines not containing Li or Fe, Mn, Ca. The colourless or pale red variety from Elba contains 0.2 p. c.; the brown variety from Windisch-Kappel contains 11.8 p. c. MgO. Black tourmaline from Andreasberg contains 17.4 p. c. FeO. These qualitative and quantitative differences show themselves in the colour of the mineral: magnesium tourmalines are yellow or brown; magnesium-iron tourmalines dark brown to black; iron tourmalines black; manganese tourmalines free from iron are red, reddish, or colourless, &c. But, notwithstanding the very great variety in the individual constituents, the constitution of the tourmalines, viewed as a group, is governed by a very simple law. This law, deduced from the examination of 32 varieties, is as follows: *Tourmalines are tribasic silicates (Drittelsilicate)*. The primary compounds may always be reduced to the following silicates:

The tourmaline group resolves itself into two great divisions. In the first division the atomic ratio $Al : Si = 1 : 2$; in the second = $2 : 3$.

Tourmalines of the first division consist of tribasic silicates represented by the formulæ $R^1AlBSi^2O^{10}$ and $R^3Al^2B^2Si^3O^{20}$. This is the most numerous division, and to it belong 25 of the tourmalines examined by Rammelsberg. They yield 30–32 p. c. alumina. Their structure is determined by the proportion of the two silicate molecules above mentioned, and it is found that the simpler ratio $1 : 1$, in which $R^1 : Al = 1 : 1$.

* $Al = Al^3 = 54.8$.

greatly predominates, having been observed in 21 representatives; and, besides these, the relation $5 : 2$, that is $R'' : \text{Al} = 2 : 3$, has been found in only four others (from Saar, Elba, Sarapulsk, Goshen).

Tourmalines of the second division consist of the tribasic silicate-molecules

$\text{R}^*\text{Al}^*\text{B}^*\text{Si}^*\text{O}^{12}$ and $\text{R}^*\text{Al}^*\text{B}^*\text{Si}^*\text{O}^{14}$. These tourmalines, even in entire crystals, are transparent, colourless, or slightly greenish or reddish, or red (precious tourmalines). They yield 42–44 p. c. alumina, and are nearly or quite free from iron; and, inasmuch as they contain but little manganese or magnesium, the silicate containing R' predominates in this case also over that which contains R''. The atomic ratio $R'' : \text{Al} = 1 : 6$ (Elba, pale green; Schaitansk, red); or $1 : 12$ (Rozena, Paris, red); or $1 : 24$ (Elba, pale red and colourless) indicates in these five varieties a variable proportion between the two silicate-molecules, viz. $(2 : 1; 5 : 1; \text{and } 11 : 1)$.

Between these two divisions, that is to say, with an intermediate proportion of $\text{Al} : \text{Si}$, lies the dark green tourmaline from Brazil, and the similar one from Chesterfield. In other respects, these varieties containing 6 p. c. FeO conform to the general law; they may be regarded as forming a third division, or as being made up of isomorphous mixtures of the other two. The latter view is that which Rummelsberg prefers; for it not unfrequently happens that the colours exhibited by an individual tourmaline crystal show that it is formed above and below, or externally and internally, of constituents which are chemically dissimilar, although analogous and isomorphous.

TRIDYMITE. A crystallised variety of silica occurring in clefts and cavities of a trachytic porphyry near Pachuca in Mexico. It forms hexagonal crystals, often in twins, and having a sp. gr. of 2.326 to 2.295 at 15° to 16° , which is that usually assigned to amorphous silica. The crystals are colourless, and have a vitreous to nacreous lustre, which, however, they lose by contact with the air (G. vom Rath, *Zeitschr. f. Chem.* [2] v. 410).

TRIETHYLSULPHINE CYANIDE, $\text{Si}^*\left\{\begin{smallmatrix} (\text{C}^2\text{H}^5)^3 \\ \text{CN} \end{smallmatrix}\right.$, is produced by digesting the corresponding iodide (v. 611) at 100° with potassium cyanide. It remains, on evaporating the alcoholic solution, as a thick syrup, which by slow evaporation over oil of vitriol yields colourless, very deliquescent needles. Heated with acids or alkalis it is resolved, with addition of the elements of water, into ethyl sulphide, propionic acid, and ammonia; also when heated with water or alcohol to 120° (Gauhe, *Zeitschr. f. Chem.* [2] iv. 622).

TRIGLYCOLLAMIC ACID. See GLYCOLLAMIC ACIDS (p. 646).

TRIMESIC ACID.

TRIMELLITIC ACID. } See MELLITIC ACID (pp. 811, 813).

TROPIC ACID. See ATROPIC ACID (p. 249).

TUNGSTEN. The following observations on the hydrates of tungstic acid have been made by Zettnow (*Pogg. Ann.* cxxx. 16, 240; *Bull. Soc. Chim.* [2] viii. 37, 174; *Jahresb.* 1867, 223). Tungstic acid separated from sodium tungstate by mineral acids at ordinary temperatures is soluble in ammonia. A hydrate only slightly soluble in ammonia, but easily soluble in sodium carbonate, is obtained by boiling $1\frac{1}{2}$ pt. neutral or 3 pts. of the acid sodium tungstate with 1 pt. of strong sulphuric mixed with a little nitric acid, till the sulphuric acid begins to evaporate; then diluting with water; washing with water, mixed towards the end of the operation with a little sulphuric acid (to prevent the tungstic acid from running through the filter); and again heating the residue with strong sulphuric acid till the latter evaporates. The washed and air-dried tungstic acid has a light lemon-yellow colour with a tinge of green:

	After drying at 50°	120° – 130°	200°
	It contains . 8.7	2.5	1.7 p. c. water
or	$2\text{WO}^3.\text{H}^2\text{O}$	$3\text{WO}^3.\text{H}^2\text{O}$	$4\text{WO}^3.\text{H}^2\text{O}$.

When ignited, it acquires a lighter colour.

The solution of sodium monotungstate is not precipitated by sulphurous, hydriodic, hydrocyanic, oxalic, or tartaric acid; but these acids do not hinder the precipitation by mineral acids. When the solution of a tungstate is heated with acetic acid, mineral acids (as in presence of phosphoric acid) do not produce a precipitate, unless the solution has been previously neutralised with ammonia. Solutions containing 1 pt. tungstic anhydride in 10,000 pts. still give a trace of blue colour with zinc and sulphuric acid, but are not precipitated or clouded by potassium ferrocyanide,

lead acetate, or stannous chloride. Solutions containing 0.005 p. c. tungstic anhydride also give with these last-mentioned reagents only a slight reaction, and at twice that degree of dilution no visible reaction occurs (lead acetate alone still produces opalescence).

For the estimation of tungstic acid in soluble neutral tungstates, Zettnow acidulates the solution with acetic acid, and precipitates it at the boiling heat with a one-tenth normal solution of lead acetate. The precipitate of neutral lead tungstate, $PbWO_4$, separates quickly towards the end of the precipitation and becomes heavy and crystalline; the end of the experiment may therefore be recognised with certainty by testing a filtered sample. Soluble acid salts must be previously converted into neutral salts by addition of sodium carbonate, and then slightly supersaturated with acetic acid; insoluble salts must be decomposed by fusion with sodium carbonate.

Zettnow has also made observations on the composition and properties of several metallic tungstates, and on the properties of metallic tungsten prepared by various processes. Observations on the tungstates have also been published by Ullik (*J. pr. Chem.* ciii. 147; *Jahresb.* 1867, p. 221).

TURACIN. A red pigment found in the wing-feathers of four species of *Turaco*. It is extracted by dilute alkalis, and may be precipitated from the solution by acids without alteration. It differs from all other known animal pigments, in the circumstance that it contains 5.9 p. c. copper, which cannot be separated without destruction of the pigment. The spectrum of this pigment exhibits two black absorption-bands. It is constant in composition, even when obtained from birds of different genus and species, as, for example, from *Musophaga violacea*, *Cerythaix albo-cristata*, and *C. porphyreolopha* (Church, *Chem. News*, xix. 265; *Gmelin's Handbook*, xviii. 420).

TURPENTINE-OIL. $C^{10}H^{16}$.—Vapour of turpentine-oil passed through a red-hot iron tube filled with fragments of porcelain, is resolved into a large number of hydrocarbons, very difficult to separate, some of which are isomeric with it (Hlasiwetz u. Hinterberger, *Zeitschr. f. Chem.* [2] iv. 380).

Turpentine-oil is easily oxidised by *potassium permanganate*. 10 pts. freshly rectified turpentine-oil agitated with 500 pts. water reduce in a few hours 28 parts of the permanganate (corresponding with the proportion $C^{10}H^{16} : O^4$), if the latter be gradually added and rise of temperature avoided; the further oxidation takes place slowly at the boiling heat. The products are: 1. An acid separated from the concentrated aqueous solution by mineral acids as a resinous body easily soluble in hot water.—2. A small quantity of a neutral volatile substance which, when the aqueous mixture is distilled, sublimes in short needles having the odour of camphor, and appearing to be either camphor, $C^{10}H^{16}O$, or a body isomeric with it (Berthelot, *Bull. Soc. Chim.* [2] vii. 136).

When turpentine-oil is gradually added to a dilute solution of *hypochlorous acid*, a yellow viscid liquid is deposited (probably a mixture of di- and tri-chlorinated turpentine-oil), whilst the aqueous solution agitated with ether gives up to that liquid a neutral syrupy substance, having the composition of the dichlorhydrin of turpentine-oil, $C^{10}H^{14}Cl_2O$. This compound dissolves slightly in water, easily in alcohol and ether; is partly decomposed by distillation; is not resinised by nitric acid; and is converted by the action of sodium on its ethereal solution into an acid which appears to have the composition $C^{10}H^{14}O^2$ (C. G. Wheeler, *Bull. Soc. Chim.* [2] x. 288).

Turpentine-oil heated with *hydriodic acid* yields: 1. Camphene hydride, $C^{10}H^{14}$. H^2 , analogous to the hydrochloride, $C^{10}H^{14}.HCl$, a liquid which boils at about 165° , is not attacked by ordinary sulphuric in the cold, and dissolves in fuming nitric acid without oxidation, yielding a nitro-compound, also in lukewarm fuming sulphuric acid, forming a sulpho-acid soluble in water; it forms a crystalline derivative with bromine.—2. Terpene hydride, $C^{10}H^{16}$. H^2H^2 , corresponding to the dihydrochloride, $C^{10}H^{14}.2HCl$, a liquid boiling at 170° – 175° , difficult to separate from the preceding, not completely soluble in fuming sulphuric acid. On adding water to the mixture, a viscid product (perhaps a polymeride) separates, having the odour of camphor.—3. A saturated hydrocarbon, $C^{10}H^{18}$, which boils between 155° and 160° ; withstands the action of bromine, sulphuric acid, nitric acid, &c.—4. Amyl-hydride or quintane, C^5H^{12} (Berthelot, *Compt. rend.* lxxvii. 327).

A hydrocarbon isomeric with turpentine-oil is formed by the decomposition of rutylene bromide (produced from diamylene, iv. 141) with alcoholic potash. It is a transparent colourless liquid, agreeing nearly in composition with the formula $C^{10}H^{16}$, and having a vapour-density = 4.32 (calc. 4.70); but it is extremely difficult to purify. It has a strong odour of turpentine, especially when exposed to the air; burns, when set on fire, with a luminous but smoky flame. When bromine is dropped into it at -17° , the first drops unite without evolution of hydrobromic acid; but on

adding a larger quantity, a violent action takes place, and hydrobromic acid is evolved. Iodine acts in a similar manner, but less strongly. Nitric acid exerts a violent oxidising action, and sulphuric acid dissolves the substance with deep brown colour. Hydrochloric acid in the gaseous state or in aqueous solution unites with it at ordinary temperatures. When the gas was passed through it for several hours at 10° , and the liquid was afterwards washed, dried, and fractionally distilled, the portion distilling between 180° and 200° decomposed with blackening and copious evolution of hydrochloric acid; and at about 110° a nearly colourless liquid distilled over, smelling of hydrochloric acid, and having nearly the composition $2C^{10}H^{16}$, HCl. The formation of this hydrocarbon from amylene may be represented by the following equations:

The hydrocarbon, $C^{10}H^{16}$, thus obtained, is probably terebene (Bauer a. Verson, *Ann. Ch. Pharm.* cli. 52).

Tawildarow (*Zeitschr. f. Chem.* [2] iv. 278) has found, in the portion of coal-tar oil boiling between 172° and 190° , a hydrocarbon having nearly the composition of a lower homologue of turpentine-oil, C^9H^{14} (*nonene* according to Hofman's nomenclature, p. 794), which is acted upon by bromine, with evolution of hydrobromic acid, and formation of the compound $C^9H^{12}Br^2$ or $C^9H^{10}Br.Br^2$.

TYROSINE. $C^9H^{11}NO^2$ (Thudichum a. Wanklyn, *Chem. Soc. J.* [2] vii. 277).—When tyrosine is treated with potassium dichromate and dilute sulphuric acid (2 grms. tyrosine, less than 10 grms. sulphuric acid, 100 c. c. water and 8 grms. dichromate), carbon dioxide is evolved, together with an odour of formic acid, and an insoluble yellow-green chrome-compound is formed, consisting of $C^9H^{11}NO^{12}$, CrO^3 , $3H^2O$. This compound is nearly insoluble in water, but dissolves slowly and without evolution of gas in hydrochloric acid. When heated, it swells up, gives off carbon dioxide and water, and leaves a mixture of chromic oxide and finely divided charcoal. This compound is formed only when a small quantity of sulphuric acid is used. With excess of sulphuric acid, the only products are carbon dioxide and water, with a little formic acid.

Tyrosine boiled with a mixture of *mercuric* and *mercurous nitrates* (containing some mercurous nitrite) forms a deep red precipitate having the composition $C^9H^9(NO^2)^2NO.Hg^2$. The mercurous salt does not take part directly in the formation of this precipitate; the entire quantity of the mercury belonging to it remains in the solution, and the function of this salt is merely to supply nitrous acid, or perhaps nitrogen dioxide. If the quantity of mercurous salt added is insufficient for this purpose, only a light flesh-coloured precipitate is formed; and when tyrosine is boiled with mercuric nitrate free from mercurous salt, and nitrogen dioxide is passed into the boiling liquid, the deep red precipitate is instantly formed (compare v. 932; also L. Meyer, *Ann. Ch. Pharm.* cxxxii. 156). This compound is very energetically attacked by alkalis, potash and ammonia forming with it a deep red solution which deposits a precipitate resembling sepia. Nitric acid dissolves the red compound, forming a red solution.

Städeler found that nitrotyrosine treated with nitric acid is converted into dinitrotyrosine (v. 934). Thudichum a. Wanklyn, however, find that this dinitro-compound is not produced, but that a nitrotyrosic acid, $C^9H^{10}(NO^2)NO^2$, is obtained, which when dissolved in water and neutralised with calcium carbonate, forms a deep red solution yielding orange-red tabular crystals, which have nearly the composition $C^9H^9Ca''(NO^2)NO^2 + 3H^2O$. If the action of the nitric acid be carried further, oxalic acid is produced.

According to Städeler, also, dinitrotyrosine is formed by the action of nitrous acid upon tyrosine. Thudichum and Wanklyn's experiments do not confirm this result. When nitrous acid (from nitric acid and arsenious oxide) is passed into water in which tyrosine is suspended, the tyrosine gradually dissolves, with yellow colour and slight evolution of gas; and on neutralising this solution with calcium carbonate, evaporating over oil of vitriol, filtering to remove a brown scum, and mixing the filtrate with lead acetate, a chocolate-coloured precipitate is formed having (at 110°) nearly the composition $C^9H^9Pb.NO^2$.

Tyrosine is not acted upon by excess of ethyl iodide at 100° ; neither is it reduced by hydriodic acid at 130° .

Constitution of Tyrosine.—The nitrogen in tyrosine may be estimated by Will a. Varrentrapp's process; consequently tyrosine does not contain any nitrogen in the form of nitril; neither is the nitrogen in the form of amidogen or imidogen, since ethyl

iodide effects no substitution. The nitrogen must therefore be altogether in direct union with the carbon. Moreover there is no hydroxyl; otherwise hydriodic acid would effect a reduction; therefore the oxygen must be in direct and complete union with the carbon. Tyrosine appears to be derived from nonane, C^8H^{18} , by substitution to a considerable extent, 3 at. hydrogen having been replaced by N^1 , and 6 at. hydrogen by 3 at. oxygen. Its constitutional formula is most probably

Its great stability shows that the grouping of the oxygen-atoms is regular. The fact that tyrosine gives no acetic acid by oxidation, shows that it does not contain ethyl in union with part of the nitrogen or with oxygen. The easy formation of carbonic acid is in harmony with the supposition that the molecule of tyrosine contains 3 mol. carbon monoxide (Thudichum u. Wanklyn; see also Hüfner, *Zeitschr. f. Chem.* [2] iv. 391).

Tyrosine heated with fuming hydriodic acid takes up 1 mol. hydrogen, and is resolved into ammonia, which appears as ammonium iodide and phloretic acid: $C^8H^{11}NO^3 + H^2 = NH^3 + C^8H^{10}O^3$; hence Hüfner (*Zeitschr.* iv. 391) regards it as

amidophloretic acid, $C^8H^9(NH^2)O^3 = C^8H^8\begin{matrix} OH \\ NH^2 \\ C^2H^3O^2 \end{matrix}$. Barth, who formerly regarded

tyrosine as ethyl-amidoparaoxybenzoic acid (v. 932), now regards it as oxyphenyl-

amidopropionic acid, $C^8H^8\begin{matrix} C^2H^4OH \\ NH^2 \\ COOH \end{matrix}$ (*Zeitschr.* vi. 113).

Tyrosine Platinchloride, $2(C^8H^{11}NO^3.HCl).PtCl_4$, is obtained in small granular crystals, by adding the hydrochloride to a slightly acid solution of platonic chloride, and leaving the solution to evaporate in a vacuum over quick lime and fragments of calcium chloride (Gintl, *ibid.* v. 704).

U

ULTRAMARINE. On the constitution of Ultramarine see W. Stein (*J. pr. Chem.* [2] iii. 39; *Chem. Soc. J.* [2] ix. 166); on the preparation of ultramarine paper, and its uses as a reagent, W. Stein (*J. pr. Chem.* ciii. 172; *Zeitschr. f. Chem.* [2] iv. 599).

URANIUM. The following method of preparing fused metallic uranium, devised by Valenciennes, is described by Peligot (*Compt. rend.* lxvii. 507). A mixture of 75 grams uranous chloride, 150 grams dry potassium chloride, and 50 grams sodium cut into pieces, is placed in a crucible and covered with potassium chloride; and this crucible is enclosed in a larger one, the space between them being packed with charcoal powder. The whole is heated in an air-furnace, and when the reaction has taken place at a red heat, the fire is strongly urged, so as to melt the metal but without volatilising the flux. The reduced uranium is found within the black very dense slag, and may be separated by lixiviation. For the success of the preparation, it is essential to exclude the moisture of the air, which would convert the uranous chloride into irreducible uranic oxide; also to protect the metal from access of air during cooling. Uranium thus prepared has a sp. gr. of 18.33.

According to Souchay (*Zeitschr. anal. Chem.* vi. 400) the precipitate formed by boiling solutions of uranic salts supersaturated with ammonium carbonate, contains in 100 pts.:

U^1O^3	CO^2	NH^3	H^1O
83.31	2.56	2.56	11.57

UREA. CH^4N^2O . The constitution of this body has lately been the subject of considerable discussion.

Basarow (*Chem. Soc. J.* [2] vi. 194) finds that urea is produced when dry ammonium carbonate, $CO^2N^2H^4$ (prepared by passing dry carbon dioxide and ammonia gased into absolute alcohol) is heated to 130° – 140° in sealed tubes; also by heating the commercial carbonate of ammonia (which appears therefore to contain carbonate) to

the same temperature. Conversely, Bunte, has lately shown (*Ann. Ch. Pharm.* cli. 181) that urea may be converted into ammonium carbamate (urethane) by heating nitrate of urea with alcohol:

These reactions show that urea is the amide of carbamic acid, a view advocated by Kolbe (*Zeitschr. f. Chem.* [2] iii. 50), and formerly by Heintz (*Ann. Ch. Pharm.* cxl. 276). If, however, carbamic acid be represented by the formula $\text{H}^2\text{N}-\text{CO}-\text{OH}$, its amide must be the same as the diamide of carbonic acid, that is to say, urea regarded as the amide of carbamic acid must be identical with carbamide:

But if carbamic acid has the constitution represented by the formula

in which the nitrogen is quinquivalent, then its amide, urea, will have a structure different from that of carbamide, viz. $\text{CO}=\text{NH}^2-\text{NH}^2$.

With regard to this question, Heintz observes (*Ann. Ch. Pharm.* cl. 73) that the representation of carbamic acid by the formula $\begin{cases} \text{NH}^2 \\ | \\ \text{CO} \\ | \\ \text{OH} \end{cases}$, and of amic acids in general by

$\begin{cases} \text{NH}^2 \\ | \\ \text{R}'' \\ | \\ \text{OH} \end{cases}$, or still more generally by $\begin{cases} (\text{NH}^2)^{n-p} \\ | \\ \text{R}^{(n)} \\ | \\ (\text{OH})^p \end{cases}$, is in accordance with the fact that such acids are never formed from monatomic, but only from polyatomic acids, whereas if the molecule were held together, not by the acid radicle, but by the nitrogen as represented by the formula, $\begin{cases} \text{R}'' \\ | \\ \text{NH}^2 \\ | \\ \text{OH} \end{cases}$, the existence of compounds like $\begin{cases} \text{R}'\text{H} \\ | \\ \text{NH}^2 \\ | \\ \text{OH} \end{cases}$ or

$\begin{cases} \text{R}'\text{R}' \\ | \\ \text{NH}^2 \\ | \\ \text{OH} \end{cases}$, would also be possible. Moreover the representation of urea as carbamide is in accordance with all its synthetical modes of formation, excepting those in which a transposition of the atoms must be supposed to take place—such as its formation from ammonium cyanate—which throw no light on its structure. The conversion of carbonyl chloride into urea by the action of ammonia is easily intelligible if urea be regarded as carbamide; for

whereas if urea has the construction represented by the formula $\text{CO}-\text{NH}^2-\text{NH}^2$, its formation in the manner just mentioned involves a transposition of the atoms; but it is not easy to see why such a transposition should take place, inasmuch as nitrogen is less inclined to form compounds in which it is quinquivalent than those in which it is trivalent. Similar remarks apply to the formation of urea from ethyl chlorocarbonate, ethyl carbonate, and the urethanes. Its formation from cyanide, $\text{CN}-\text{NH}^2$, is also very easily explained if it be supposed to consist of carbamide, being, in fact, analogous to a large number of the transformations which cyanogen-compounds undergo under the influence of water (Heintz).

On the other hand, the identity of urea and carbamide, which seems to follow from the preceding considerations, is in discordance with the fact established by Wanklyn & Gamgee, that urea differs from amides in general in its behaviour with alkaline permanganates, inasmuch as when oxidised by excess of potassium permanganate in alkaline solution, it gives off all its nitrogen in the free state, whereas when amides

are thus treated, the nitrogen is wholly converted into nitric acid. Wanklyn a. Gamgee represent urea by the formula $C \begin{pmatrix} (NH)^n \\ NH^2 \\ OH \end{pmatrix}$, but do not give any specific reasons for the adoption of this particular formula.

Bunte (*Ann. Ch. Pharm.* cli. 184) points out that the question about the relation of urea to carbamide might be elucidated by ascertaining the greatest number of isomeric substitution-products that can be formed by the substitution of any particular radicle, ethyl, for example, in its molecule. For in carbamide, $H^2N-CO-NH^2$, in which both atoms of nitrogen are trivalent, and all the nitrogen- and hydrogen-atoms are symmetrically disposed, the number of such possible isomeric derivatives must be less than in urea regarded as $CO=NH^2-NH^2$, in which one atom of nitrogen is quinivalent, and the arrangement is not symmetrical. For example, carbamide can yield but one monoethylated derivative; whereas urea, if it consists of $CO=NH^2-NH^2$, may yield the two isomeric ethyl-urens:

The former of these, by partial reduction to carbamic acid, would yield ethyl-carbamic acid and ammonia, whereas the latter would yield carbamic acid and ethylamine.

Preparation of Urea.—According to J. Williams (*Chem. Soc. J.* [2] vi. 68) lead cyanate is much better adapted for the preparation of urea than the potassium salt. It is merely necessary to digest equivalent quantities of this lead salt and ammonium sulphate at a moderate heat, with a sufficient quantity of water, then filter and evaporate. Compound ureas may be prepared in like manner by digesting the sulphates of the corresponding amines with cyanate of lead.

Reactions.—1. Urea heated with carbon bisulphide to 100° in a sealed tube, yields carbon oxy-sulphide and ammonium sulphocyanate:

With alcohol and carbon bisulphide the products are mercaptan, carbon dioxide, and ammonium sulphocyanate:

(Ladenburg, *Zeitschr. f. Chem* [2] v. 253).—2. Urea heated with aldehyde-ammonia and ammonium acetate yields aldehyde, NC^2H^4 (p. 82):

(Ador a. Baeyer, *ibid.* iv. 724).—3. With glycocine urea yields hydantoic acid (p. 702).—4. Respecting the reaction of urea with amido-benzoic acid, see page 318.

Compounds of Urea with Phosphoric Acid.—Lehmann (*Buchn. Repert.* xv. 224) described a crystalline compound of phosphoric acid and urea, which he obtained from pigs' urine after the animals had been fed upon pure clover. To this compound he assigned the improbable formula $CON^2H^4.2H^2O.P^2O^5 + aq.$ Schmelzter a. Hirnbäum (*Zeitschr. f. Chem.* [2] v. 206) have obtained the same compound, together with ammonium phosphate, $(NH^4)H^2PO^4$, by dissolving urea in a concentrated solution of orthophosphoric acid, evaporating in a vacuum over oil of vitriol, and recrystallising the residual mass from water. The urea phosphate forms large rhombic crystals, having the composition $CON^2H^4.H^2PO^4$. The crystals are permanent in dry air, dissolve easily in water and alcohol, sparingly in ether; heated above 100° they decompose, with brisk effervescence, into ammonia, carbon dioxide, and metaphosphoric acid:

The phosphoric acid in this compound is not neutralised by the urea, inasmuch as the solution does not precipitate magnesium sulphate or silver nitrate except on addition of ammonia. When evaporated with potassium or sodium carbonate, it is resolved into urea and phosphoric acid, which unites with the alkali.

Another phosphate, containing $3CON^2H^4.2H^2PO^4$, was once obtained by evaporating a mixture of phosphoric acid with excess of urea without the aid of heat. Its aqueous solution when heated yielded a crystalline precipitate of cyanuric acid, formed according to the equation $3CON^2H^4 = 3NH^3 + C^3H^3N^3O^3$. A similar decomposition of urea takes place on heating it with phosphoric anhydride (v. 950), as observed by Weltzien (*Ann. Ch. Pharm.* cvii. 219).

Substitution-derivatives of Urea.

Acetyl-urea, $\text{CON}^2\text{H}^1(\text{C}^2\text{H}^3\text{O})$, is formed when 1 pt. of urea is heated with 2 pts. of acetic anhydride till the latter boils, the acetyl-urea then separating out on cooling.

Chloracetyl-urea, $\text{CON}^2\text{H}^1(\text{C}^2\text{H}^3\text{ClO})$, is formed by the action of chloracetyl chloride on urea; it appears to be acted upon by potassium cyanide (Jazukowitsch, *ibid.* 234).

Amyl-ureas. (Wurtz, *Bull. Soc. Chim.* [2] vii. 141).—**Primary Amyl-urea**, $\text{C}^1\text{H}^1\text{N}^2\text{O} = \text{CON}^2\text{H}^1(\text{C}^3\text{H}^{11})$, formed by the action of ammonia on amyl cyanate (i. 754), crystallises in glistening needles which melt at 120° , and dissolve in 28.1 pts. of water at 27° .

Secondary Amyl-urea or **Pseudo-amylene-urea**, $\text{CON}^2\text{H}^1(\text{C}^3\text{H}^{10}\text{H}) = \text{CON}^2\text{H}^1(\text{CH}^3)(\text{C}^3\text{H}^9)$, is produced by the action of ammonia on amylene cyanate (p. 114), and may be prepared by mixing amylene hydriodide with silver cyanate at a very low temperature, then distilling, and agitating the strong-smelling distillate with excess of aqueous ammonia. Secondary amyl-urea then separates in the course of 24 hours, as a crystalline mass, which may be purified by recrystallisation from hot water. It forms beautiful needles, which melt at 151° , and then sublime partially, with evolution of ammonia; dissolves in 79.3 pts. of water at 27° , easily in alcohol. Heated with strong potash-ley to 140° – 150° , it is resolved into carbon dioxide, ammonia, and isoamylamine (p. 116). In contact with nitric acid diluted with an equal volume of water, it is converted into an oily nitrate, which in contact with dry air gives off nitric acid and becomes covered with crystals; the mother-liquor yields crystals of ordinary nitrate of urea.

Secondary Diamyl-urea or **Pseudo-diamylene-urea**, $\text{C}^{11}\text{H}^2\text{N}^2\text{O} = \text{CON}^2\text{H}(\text{CH}^3)(\text{C}^3\text{H}^9)(\text{C}^3\text{H}^{11}) = \text{CON}^2\text{H}^2(\text{C}^3\text{H}^{10}.\text{H})^2$, is formed, together with potassium carbonate, by heating amylene cyanate with caustic potash in a closed flask:

It sublims in the flask in colourless needles, which may be purified by dissolving them in alcohol and mixing the solution with water till it begins to show turbidity. It is very volatile, sublims without melting, is nearly insoluble in water, and is precipitated by water from its solution in nitric acid. It is not attacked by potash at the temperature of boiling oil.

Amylene cyanate is likewise resolved into carbonic anhydride and secondary amyl-urea, by prolonged contact with water.

Benzoyl-urea, $\text{CON}^2\text{H}^1(\text{C}^7\text{H}^5\text{O})$, is obtained by heating equal parts of benzoic anhydride and urea to 140° – 150° . The whole mass crystallises on cooling, and on treating it with alcohol, benzamide and the excess of benzoic anhydride are dissolved, while cyanuric acid and benzoyl-urea remain behind. By repeated crystallisation from ammoniacal water, the cyanuric acid may be removed and the benzoyl-urea obtained in colourless needle-shaped crystals; the quantity is, however, but small (Geuther, Schertz a. Maish, *Zeitschr. f. Chem.* [2] iv. 299).

Formyl-urea, $\text{C}^2\text{H}^1\text{N}^2\text{O}^2 = \text{CON}^2\text{H}^1(\text{CHO})$, isomeric with oxamide, is produced by heating equivalent quantities of urea and formic acid, first in the water-bath, afterwards over the open fire till gas begins to escape. The liquid on cooling solidifies to a pulp of small white crystals of formyl-urea, easily soluble in water, slightly soluble in cold, more easily in hot absolute alcohol. From the alcoholic solution it crystallises out unaltered on evaporation, but not from the aqueous solution, being resolved by the water into formic acid and urea. When boiled with potash, it gives off ammonia and yields formic acid, but not in the cold. Formyl-urea melts at 159° and decomposes at a higher temperature, giving off ammonia and hydrocyanic acid, and leaving cyanuric acid mixed with porous charcoal. At 190° an oily compound is also formed, probably formamide. At 200° the still viscid residue swells up, blackens, and leaves porous charcoal. Formyl-urea is not obtained by the action of cyanic acid vapour on formamide, the products being cyamelide and hydrocyanic acid (Geuther, Schertz a. Maish).

Hydroxyl-urea, $\text{CON}^2\text{H}^1(\text{OH})$.—Already described (p. 725).

Oxybenzoyl-urea, $C^6H^5N^2O^2 = CON^2H^2(C^6H^5O)^*$, is formed by heating oxybenzamic acid (p. 318) to 180° – 190° . The boiling ammoniacal solution gives with hydrochloric acid a precipitate insoluble in water, alcohol, and ether, crystalline when formed in small quantities, amorphous in large quantities. The barium salt of oxybenzoyl urea $(C^6H^5N^2O^2)^2Ba + 3H^2O$ is easily decomposed by the weakest acids and by ammonia. The silver salt, $C^6H^5N^2O^2Ag$, is anhydrous (Menschutkin, *Zeitschr. f. Chem.* [2] v. 53). The same compound appears to have been obtained by Griess (*ibid.* iv. 389).

Pseudo-hexylene-urea, $C^6H^{10}N^2O^2 = CON^2H^2(C^6H^{11}H)$, is obtained by heating a mixture of silver cyanate and hexylene hydriodide (from mannite) to 50° – 60° , and agitating the unpleasant-smelling liquid which then passes over with aqueous ammonia. Pseudo-hexylene-urea then remains as a solid mass, and after repeated crystallisation from water, forms slender needles, which dissolve easily in boiling water, in alcohol and in ether, melt at 127° , and boil with partial decomposition at about 220° . Heated with strong potash-ley to 230° – 250° , it decomposes, with evolution of ammonia and formation of an oily liquid, probably isohexylamine (Chydenius, *Bull. Soc. Chim.* [2] vii. 481).

Tolylene-ureas. (Strauss, *Ann. Ch. Pharm.* cxlviii. 157).—**Tolylene-diurea**, $(C^6H^4N^2O^2 = (CON^2H^2)^2(C^6H^4)^*)$, is formed when 1 mol. dissolved tolylenediamine sulphate is gradually added to a solution of 2 mol. potassium cyanate cooled with ice. A small quantity of carbon-dioxide is evolved, and a white powder separates. On evaporating to dryness and exhausting the residue with alcohol, the tolylene-urea remains together with potassium cyanate, and may be obtained pure by crystallisation from boiling water. It forms micaceous crystalline scales melting at 220° . It is nearly insoluble in alcohol, and very sparingly soluble in water, even at the boiling heat, soluble in hydrochloric and in nitric acid. When dry hydrochloric acid gas is passed over this body, 2 mol. HCl are taken up, and on dissolving the product in alcohol, the solution yields a crystalline body, which appears to be a tolylene-urea isomeric with monocyanate of tolylene-diamine. These two tolylene-ureas may be represented by the following constitutional formula:

UREA, SULPHURETTED. CSN^2H^4 (J. E. Reynolds, *Chem. Soc. J.* [2] vii. 1).—This compound, the sulphur-analogue of urea, is produced from ammonium sulphocyanate in the same manner as urea from ammonium cyanate. About 500 grams of well-dried ammonium sulphocyanate are heated to about 170° for about two hours in a flask placed in an oil-bath; the flask is then left to cool, and as soon as the temperature of the fused mass has sunk to 100° , it is mixed with an equal weight of water at 80° , and the solution is quickly filtered through a small plug of cotton, to remove a small quantity of a black substance which always forms in the process. The solution, after a few hours, deposits silky needles of the sulphuretted urea, which by recrystallisation from the smallest possible quantity of water may be obtained in long slender needles or in very short thick prisms belonging to the rhombic system. It melts at 149° ; does not deliquesce in moderately warm air; dissolves easily in water and alcohol, sparingly in ether. The solutions froth slightly on agitation, have a neutral reaction and somewhat bitter taste, are not coloured by ferric chloride. By heating with water to 140° for several hours, the urea is reconverted into ammonium sulphocyanate, and by prolonged heating to 100° in a sealed tube with potassium hydrate, it yields ammonia, together with potassium sulphhydrate, carbonate, and a small quantity of sulphocyanate:

It is decomposed in the same manner by sulphuric and hydrochloric acids. By boiling with dilute nitric acid, the sulphur is oxidised to sulphuric acid. With nitrous acid and hypochlorites it gives off nitrogen, also when treated with a large excess of potassium permanganate, the sulphur being in that case oxidised to sulphuric acid. Heated on platinum foil it volatilises without residue; when heated in a tube, it melts, then boils up, giving off ammonium sulphide, carbon bisulphide and ammonia (?), then blackens, and on continued heating yields a yellow oily distillate, while a white mass resembling hydromellone remains behind.

The nitrate, $CSN^2H^4 \cdot HNO^3$, is obtained as a crystalline precipitate on mixing a nearly saturated solution of the sulphurea with nitric acid of sp. gr. 1.25, keeping the

liquid cool. On gradually adding a nearly neutral solution of auric chloride to the saturated aqueous solution till the resulting red precipitate begins to be permanent, and leaving the solution to evaporate, the *gold-salt*, $2\text{CSN}^{\cdot}\text{H}^{\cdot} \cdot \text{AuCl}_3$, is obtained in nacreous monoclinic crystals. With excess of the gold solution a very unstable reddish-yellow precipitate is obtained. A nearly neutral solution of *platinic chloride* added to a slight excess of the solution of the sulphurea produces a red crystalline precipitate, appearing under the microscope as an aggregate of long prismatic feathery crystals.

Reynolds assigns to this precipitate the formula $\left\{ \begin{smallmatrix} \text{CSN}^{\cdot}\text{H}^{\cdot} \\ \text{Cl}^{\cdot} \end{smallmatrix} \right\}^2 \text{PtHCl}$. When on the other hand the solution of the urea is added to an acid solution of platinic chloride, a brown precipitate is formed, regarded by Reynolds as $\text{CSH}^{\cdot}\text{N}^{\cdot}\text{Cl}^{\cdot}\text{Pt}$.^{*} When a solution of the sulphurea is heated with *silver nitrate*, the resulting precipitate redissolves, and if the hot solution containing free nitric acid be left to cool, a crystalline mass is deposited, consisting of the unstable silver-compound $(\text{CSN}^{\cdot}\text{H}^{\cdot})_2\text{Ag}_2\text{O} + 4\text{H}_2\text{O}$. A neutral solution of *mercuric nitrate* added to a rather dilute solution of the sulphurea, produces, after some time, a crystalline precipitate, apparently consisting of $(\text{CSN}^{\cdot}\text{H}^{\cdot})_2 \cdot 3\text{HgO} + 3\text{H}_2\text{O}$.

Sulphurea heated with *silver oxide* and water, is converted into ordinary urea (Reynolds). According to Hofmann, on the other hand, it is converted, by digestion, with oxide of silver, lead, or mercury, into dicyanodiamide $\text{C}^2\text{H}^{\cdot}\text{N}^{\cdot}$:

Dicyanodiamide melts at 20° , and forms with silver nitrate the compound $\text{C}^2\text{H}^{\cdot}\text{N}^{\cdot} \cdot \text{AgNO}_3$. Its solution in hydrochloric acid yields on evaporation large tables of the hydrochloride of *dicyanodiamidine*, which, on addition of platinic chloride, deposits a platinum salt crystallising from boiling water in tufts of needles having the composition $2(\text{C}^2\text{H}^{\cdot}\text{N}^{\cdot}\text{O} \cdot \text{HCl})\text{PtCl}_4$. Dicyanodiamidine is likewise formed when sulphurea is desulphurised in presence of ammonia (Hofmann, *Deut. chem. Ges. Ber.* 1869, 600; *Zeitschr. f. Chem.* [2] vi. 158).

UREIDES or **CONDENSED UREAS** (Schiff, *Compt. rend.* lxx. 801, lxxv. 454; *Bull. Soc. Chim.* [2] ix. 323; xi. 312; *Zeitschr. f. Chem.* [2] iv. 186, 593; in detail: *Ann. Ch. Pharm.* cli. 186).—These names are applied to a series of compounds resulting from the combination of several molecules of urea with aldehyde-residues, according to the general formula,

Diureides, $\left\{ \begin{smallmatrix} \text{CON}^{\cdot}\text{H}^{\cdot} \\ \text{CON}^{\cdot}\text{H}^{\cdot} \end{smallmatrix} \right\} \text{C}^{\cdot}\text{H}^{\cdot}$, are produced by the action of aldehydes on aqueous or alcoholic solutions of urea. They are well crystallised compounds insoluble in water and ether, slightly soluble in alcohol. They begin to decompose at their melting points, generally yielding ammonia, cyanuric acid, and the corresponding hydramide:

Triureides, $\left\{ \begin{smallmatrix} \text{CON}^{\cdot}\text{H}^{\cdot} \\ \text{CON}^{\cdot}\text{H}^{\cdot} \\ \text{CON}^{\cdot}\text{H}^{\cdot} \end{smallmatrix} \right\} \text{C}^{\cdot}\text{H}^{\cdot}$, are formed by the direct action of aldehydes on pulverised urea. They are distinctly crystallised compounds resembling the diureides, and decompose at high temperatures, according to the equation:

In particular cases, *e.g.* in the formation of dibenzotriureide, a higher temperature (100° – 120°) must be applied; in this case also a slight excess of urea is necessary. The product must always be treated with water and with ether, to free it from adhering urea or aldehyde.

By the action of aldehydes in excess at 120° – 140° on the di- and tri-ureides, the more condensed combinations are obtained, *e.g.*:

These compounds are gelatinous in the moist state, and shrink together in drying;

* Improbable on account of the uneven number of the atoms of H, N and OI taken together.

they are somewhat soluble in alcohol and ether, but lose this solubility when dry. By means of cyanthol it is possible to bind together 12 molecules of urea; thus:

In the preparation of the more highly condensed ureas, it is possible to use aldehydes different from those which have been employed for the preparation of the di- or tri-ureides; in this manner are formed

Substitution-products of aldehydes also yield condensed ureas; nitrobenzoic aldehyde, for example, yields the corresponding diureide and tetraureide in the crystalline state. Condensed ureas are likewise formed from unsaturated aldehydes, e.g. acryl-diureide, $(\text{CON}^2\text{H}^3)(\text{C}^2\text{H}^4)$, from acrolein.

By prolonged contact with boiling water or dilute acids, the polyureides are resolved into urea and aldehydes. Aldehydes containing hydroxyl, such as salicylic aldehyde, yield polyureides possessing alcoholic properties.

For the detailed description of the condensed ureas, see *Ann. Ch. Pharm.* cli. 180.

URIC ACID. $C^4H^4N^2O^3$.—For the purification of uric acid prepared from guano, W. Gibbs (*Sill. Am. J.* [2] xlviii. 215) dissolves the crude acid in potash, avoiding a large excess of the alkali; adds potassium dichromate (about 5 p. c. of the uric acid); boils for a short time; then dilutes the liquid with an equal volume of water, agitates it briskly with animal charcoal, and filters. On adding hydrochloric acid, the uric acid is still precipitated with a slight yellow colour. It is left to settle, separated from the liquid by decantation, and finally boiled several times with strong hydrochloric acid till it becomes perfectly white, and dissolves without colour in potash. By this method, a kilogram of uric acid having a deep yellow colour, may be rendered perfectly white in the course of an hour.

When uric acid is heated with a solution of potassium or sodium nitrite in presence of sulphuric acid, brisk effervescence takes place; the uric acid is completely dissolved; the liquid contains alloxan and alloxantin, and when evaporated over the water-bath, yields a considerable quantity of crystalline parabanic acid, together with a small quantity of a red flocculent substance, and a still smaller quantity of a substance which dissolves in water with bright blue fluorescence. With acetic in place of sulphuric acid, the reaction is very different; the uric acid still dissolves with effervescence as before, but the filtered solution deposits a very bulky salt, which—when potassium nitrite is used—has the composition $C^4H^4KN^2O^3$. The corresponding acid, $C^4H^4N^2O^3$, called stryphnic acid (from *στυφνος*), on account of its bitter astringent taste, may be separated from the purified potassium salt by a mineral acid, in small yellow granular crystals soluble in hot water, and separating almost completely on cooling. It is monobasic, and its salts, excepting the lead salt, are soluble in hot water and crystallise in needles. Its formation from uric acid is represented by the equation:

The quantity of stryphnic acid obtained, was, however, much less than this equation requires. The mother-liquors from which it was deposited contained allantoin, formed according to the equation:

No other fixed products were observed; the evolved gas contained nitrogen as well as carbon dioxide and nitrogen dioxide (Gibbs, *loc. cit.*).

Socoloff (*Zeitschr. f. Chem.* [2] v. 78) gives a different account of the action of nitrous acid upon uric acid. According to his experiments, the first products of the action of potassium nitrite and acetic acid upon uric acid, are urinic acid $C^4H^4N^2O^3$ (p. 1120), and glycollic acid, $C^2H^2O^3$, together with nitrogen tetroxide and free nitrogen:

But the nitrogen tetroxide is immediately decomposed by the water, forming nitric and nitrous acids, by which the glycollic acid is further oxidised to oxalic acid, so that the final products are those represented by the equation :

The quantity of urinilic acid obtained is, however, less than that which corresponds to these equations, the deficiency being due to the formation of secondary products (perhaps to the reaction described by Gibbs).

Uric acid heated in a sealed tube to 160° – 170° with a cold saturated solution of *hydriodic acid*, is decomposed, with formation of ammonium iodide, carbon dioxide and glycocine :

The portion of the uric acid which appears in the form of carbon dioxide and ammonia, may be regarded as derived from 3 mol. cyanic acid or 1 mol. cyanuric acid, and in this sense uric acid may be regarded as built up from residues of glycocine and cyanuric acid, just as hippuric acid is made up of residues of glycocine and benzoic acid. Uric acid may accordingly be represented by either of the following constitutional formulæ :

or

(Strecker, *Zeitschr. f. Chem.* [2] iv. 215). On the structural formation of uric acid and its derivatives, see further (Strecker, *ibid.* 362).

URINILIC ACID. $\text{C}^{\text{H}}\text{H}'\text{N}'\text{O}^{\text{S}}$.—A tribasic acid, produced, according to Socoloff (*loc. cit.*), by the action of nitrous acid (potassium nitrite and acetic acid) on uric acid. It is slightly soluble in water, easily soluble in alkalis and alkaline carbonates, and is precipitated therefrom by hydrochloric acid, as a heavy yellow crystalline powder; from a boiling aqueous solution it separates in short thick colourless prisms. Heated with nitric acid of sp. gr. 1.30 to 1.35, it dissolves without evolution of gas, and the solution on cooling deposits small greenish, flat crystalline needles of a new acid. On further heating the nitric acid solution, red fumes are evolved, and the new acid no longer separates. Urinilic acid does not dissolve in strong sulphuric acid at ordinary temperatures.

The urinilates of the *alkali-metals* crystallise well, are very soluble in water, nearly insoluble in alcohol. Those of the *earth-metals* are white crystalline precipitates, insoluble in water and in acetic acid. Some of the salts, the copper salt for example, after drying, absorb water with great rapidity. The potassium, barium, strontium, and calcium salts are trimetalllic and anhydrous. The *di-argentic salt*, $\text{C}^{\text{H}}\text{H}'\text{N}'\text{O}^{\text{S}}\text{Ag}^{\text{S}}$, is a white pulverulent precipitate, which turns brown when exposed to light or boiled with water. The *tri-argentic salt*, $\text{C}^{\text{H}}\text{H}'\text{N}'\text{O}^{\text{S}}\text{Ag}^{\text{S}}$, is precipitated from a slightly alkaline solution of the potassium salt, as a white gelatinous mass which blackens quickly, especially when heated or exposed to light. The *cadmium salt* is a white crystalline powder containing $\text{C}^{\text{H}}\text{H}'\text{N}'\text{O}^{\text{S}}\text{Cd} + 3\text{H}^{\text{S}}\text{O}$. The *cupric salt*, $\text{C}^{\text{H}}\text{H}'\text{N}'\text{O}^{\text{S}}\text{Cu} + 4\text{H}^{\text{S}}\text{O}$, is precipitated, on mixing cold dilute solutions of the potassium salt and cupric sulphate, in short slender needles, having exactly the colour of cuprous oxide; from hot solutions, in greenish-brown flakes, which are gradually converted into the red needles (Socoloff).

UROMELANIN. $\text{C}^{\text{H}}\text{H}'\text{N}'\text{O}^{\text{S}}$ (Thudichum, *J. pr. Chem.* civ. 257; *Zeitschr. f. Chem.* [2] v. 31).—A colouring matter of urine, which separates, on treating urine with sulphuric acid, as a hard, brittle, shining black mass (Preuss's peculiar black matter), insoluble in water, slightly soluble in alcohol, very soluble in the fixed alkalis and in ammonia, from which solutions it is precipitated by acids. From solution in a small quantity of ammonia it is precipitated by most soluble salts of the *earth-metals* and heavy metals. Silver nitrate precipitates it, after addition of acetic acid. By dry distillation it gives off white vapours condensing to a neutral oil, in which mercuric nitrate forms a red precipitate. Nitric acid dissolves uromelanin, forming a dark red solution, from which water throws down an orange-red mass. Fuming sulphuric acid dissolves uromelanin with purple-red colour, and water reprecipitates it from the recently prepared solution, but only partially, after long standing.

By the action of chlorine, a brown substance soluble in alcohol is produced, to which Thudichum assigns the formula $C^{20}H^{18}Cl^3N^3O^{10}$.

Uromelanin forms with barium, calcium, zinc, lead, and silver, a number of salts containing very variable quantities of metal; thus the barium salts contain from 7.2 to 13.75 p. c. barium, the silver salts from 13.4 to 19.77 p. c. silver. They are black, amorphous, partly gelatinous precipitates. *Mercuric nitrate* added to the acetic acid solution of uromelanin forms a red precipitate.

For details respecting the origin and the physiological and pathological significance of uromelanin, see the original paper.

On the colouring matters of urine, see further, *Gmelin's Handbook*, xviii. 407-412.

UVITIC ACID. $C^8H^8O^4$. Syn. with MESIMIC ACID (p. 821).

V

VALERIC or VALERIANIC ACID. $(C^5H^{10}O^2 \rightleftharpoons C^4H^9.COOH)$.—This acid admits of four modifications, represented by the following formulæ:

The third of these is not yet known. The first is produced by oxidation of the recently discovered normal amylic alcohol (Lieben a. Rossi, p. 106); also by the action of ethyl iodide and metallic silver on β isopropionic acid (p. 961):

(W. v. Schneider, *Zeitschr. f. Chem.* [2] v. 343). It smells like butyric acid and boils at 185° (Lieben a. Rossi).

The second modification is the ordinary valeric acid produced by oxidation of the amylic alcohol of fermentation; and of this there are two subordinate modifications, one active to polarised light, the other inactive, produced respectively from the active and inactive modifications of amylic alcohol. The active acid boils at 170° , and turns the plane of polarisation 43° to the right in a column 50 centimetres long; the inactive acid boils at 175° (Petler, *Chem. Soc. J.* [2] vi. 74). These modifications probably depend upon physical isomerism rather than on metamorphism—in other words, they are due to difference of arrangement in the molecules of the acid, rather than in the arrangement of the atoms within the molecules.

Ordinary valeric acid is produced by reduction of angelic acid with hydriodic acid and red phosphorus (Ascher, p. 157).

The fourth modification, $C(CH^3)^3.CO^2H$, has been quite recently obtained from tertiary butylic alcohol or trimethyl-carbinol (Butlerow, *Zeitschr. f. Chem* [2] vi. 243).

By oxidising valeric acid (the ordinary active acid) with manganese dioxide and dilute sulphuric acid, Veiel (*Ann. Ch. Pharm.* cxviii. 160) obtained a small quantity of methyl valerate. Veiel also states, in direct contradiction to Liebig (l. 250), that when a mixture of butyric and valeric acids partly saturated with an alkali is distilled, the valeric acid passes over, and the butyric acid remains behind.

Sodium valerate in aqueous solution is slowly attacked by bromine at ordinary temperatures, more quickly when heated, very quickly in sunshine, forming carbonic

acid, a small quantity of butyl bromide, and a considerable quantity of substitution-products of the latter. Nearly a third of the liquid product consists of butylene bromide (Chapman a. Smith, *Chem. Soc. J.* [2] vii. 185).

Ethyl valerate is attacked by sodium with but slight evolution of gas, yielding, according to Greiner (*Zeitschr. f. Chem.* [2] ii. 460; *Jahresb.* 1866, p. 320) a crystalline acid, $C^2H^3O^2 = C^2H^2(C^2H^2)(C^2H^2O)O^2$, called *divalerylene-valeric acid*, together with sodium ethylate and alcohol:

According to Wanklyn (p. 590), ethyl valerate is decomposed by sodium in the same manner as ethyl acetate, yielding sodium trivaleryl and sodium ethylate; thus

Greiner's divalerylene-valeric acid is probably the same as hydrogen-trivaleryl.

Isopropyl Valerate. $C^4H^9.CO^2CH(CH^3)^2$.—See PROPYL-COMPOUNDS (p. 966).

On the estimation of valeric acid, see Zavatto a. Sestini (*Zeitschr. anal. Chem.* 1869, p. 389).

Amidovaleric Acid. $C^2H^2(NH^2)O^2$. *Butyl-alanine*.—This compound, homologous with leucine (amidocaproic acid), is formed, as observed by Cahours (v. 978), by the action of ammonia on bromovaleric acid. The brominated acid is heated with strong aqueous ammonia to 100° for 24 hours; the liquid, freed from excess of ammonia, is treated with hydrated lead oxide; the filtrate, freed from lead by hydrogen sulphide, is evaporated to a syrup; and the crystalline mass which separates is washed with a mixture of alcohol and ether, and recrystallised from alcohol. It forms colourless laminae resembling leucine, nearly opaque when dry, appearing under the microscope as very flat monoclinic prisms, easily soluble in water, nearly insoluble in cold alcohol or ether, sparingly soluble in boiling alcohol. The aqueous solution is neutral to litmus. The acid sublimes without fusion in snowy masses; when it is quickly heated, alkaline oil-drops (butylamine) collect above the sublimate. It is not decomposed by cold caustic soda. The *hydrochloride* $C^2H^2NO^2.HCl$ crystallises over oil of vitriol in tables permanent in the air, insoluble in ether, but easily soluble in water and in alcohol; the concentrated solution is not precipitated by platinic chloride. The *nitrate* $C^2H^2NO^2.HNO^2$ is a radio-crystalline mass, very soluble in water and alcohol, insoluble in ether, melting when heated and then detonating with evolution of red fumes. *Cupric amidovalerate*, $(C^2H^2NO^2)^2Cu$, separates from a solution of the acid mixed with cupric acetate, on heating, in transparent scales slightly soluble in hot water. The *silver salt*, $C^2H^2NO^2Ag$, separates on adding ammonia to a hot solution of the acid mixed with silver nitrate, in spherical groups of crystals, nearly insoluble in cold, sparingly soluble in hot water, and gradually turning grey on exposure to light (Fittig a. Clark, *Ann. Ch. Pharm.* cxxxix. 199).

Bromovaleric Acid. $C^2H^2BrO^2$.—Fittig a. Clark (*Ann. Ch. Pharm.* cxxxix. 199) have confirmed the observation of Borodine (v. 978), that this acid cannot be distilled without decomposition. The acid prepared by heating dehydrated valeric acid with bromine to 120° – 130° , and purified by passing dry air through it, decomposes at each distillation, even below 100° , yielding hydrobromic and valeric acids, together with a carbonaceous mass. According to Borodine (*Zeitschr. f. Chem.* [2] v. 342), silver valerate treated with bromine, yields Schützenberger's valerate of bromine or bromovaleric anhydride.

Chlorovaleric acid, $C^2H^2ClO^2$, is formed when 1 mol. sodium valerate and 1 mol. hypochlorous acid (obtained by passing chlorine through water in which levigated mercuric oxide is suspended), are brought together in a cooled vessel placed in the dark:

It cannot, however, be separated by distillation from unaltered valeric acid, inasmuch as it is decomposed by heat. When a solution of sodium valerate and sodium hypochlorite is left to itself for some weeks, then acidulated with hydrochloric acid and treated with ether, the ether dissolves out chlorovaleric acid (Schlebusch, *Ann. Ch. Pharm.* xlii. 322).

VALERIC ALDEHYDE. C^2H^2O .—This compound heated for some time to 240° in sealed tubes, yields water, a liquid boiling between 190° and 195° , and several condensation-products boiling at higher temperatures. The compound boiling

at 190°–195° has the composition C^5H^8O , and oxidises very readily on exposure to the air (J. Riban, *Bull. Soc. Chim.* xiii. 24).

VALERIC CHLORIDE. C^5H^9OCl .—This compound does not act in the cold, either on dry oxalic acid, or on sodium-amalgam; but when a pasty amalgam containing 2 p. c. sodium is brought in contact with a mixture of the chloride and dry oxalic acid, a reaction takes place, attended with a slight rise of temperature; and if fresh amalgam be gradually added, with continual agitation, taking care that the temperature does not rise too high, till the mass is converted into a dry powder no longer smelling of valeric chloride—water then added, and the mixture distilled, after neutralisation with sodium carbonate—an oil passes over, containing valeric aldehyde, amyl alcohol, amyl valerate, and its products of oxidation, viz. valeric aldehyde and amyl valerate, together with a peculiar oil of higher boiling point (Baeyer, *Zeitschr. f. Chem.* [2] v. 399).

VALEROLACTIC or OXYVALERIC ACID. $C^5H^9O^2 = C^5H^8(OH).COOH$.—*Ethyl-lactic acid* (iii. 463). Produced by heating bromovaleric acid with silver oxide and water. The solution filtered from silver bromide and freed from dissolved silver by hydrogen sulphide, is filtered and concentrated; the calcium salt which crystallises out is converted into a zinc salt; and the latter is decomposed by hydrogen sulphide (Fittig, a. Clark). It may also be prepared by digesting a mixture of chlorovaleric and valeric acid with excess of caustic baryta; on removing the baryta with sulphuric acid, and evaporating the filtrate, the oxyvaleric acid remains as a brownish syrup, which may be purified with animal charcoal (Schlebusch, *Ann. Ch. Pharm.* cxli. 322).

Oxyvaleric acid crystallises from a solution evaporated to a syrup over oil of vitriol in large rectangular tables, not deliquescent, easily soluble in water, alcohol, and ether; it melts at 80°, and volatilises with vapour of water, slowly also at 100° in the air-bath (Fittig a. Clark).

Most of the oxyvalerates are soluble in water. The *sodium salt*, $C^5H^8O^2Na$, forms warty crusts, easily soluble in water and in alcohol. The *barium salt*, $(C^5H^8O^2)^2Ba$, is an amorphous light yellowish mass. The *calcium salt*, $2(C^5H^8O^2)^2Ca + 3H^2O$ (or perhaps $(C^5H^8O^2)^2Ca + 2H^2O$), forms crystalline crusts more soluble in hot than in cold water. The *copper salt*, $(C^5H^8O^2)^2Cu + H^2O$, is deposited from a solution of the calcium salt mixed with cupric acetate, in light green prisms, which give off their water at 170°. The *zinc salt*, $(C^5H^8O^2)^2Zn$, separates from a concentrated solution of the calcium salt mixed with zinc chloride, in bulky crystalline masses, slightly soluble in water, insoluble in alcohol. The *silver salt*, $C^5H^8O^2Ag$, is a bulky precipitate, which separates from hot water in feathery crystals.

VALERYLENE. C^5H^8 . *Quintine* (Reboul, *Compt. rend.* lxiv. 284; *Bull. Soc. Chim.* [2] viii. 190).—This quadrivalent hydrocarbon and its bromine-compounds have been already described (v. 981). It unites slowly in the cold, easily at 100° in sealed tubes with fuming hydrochloric acid, and the product washed with alkaline water and submitted to fractional distillation, yields the mono- and dihydrochloride of valerylene, together with unaltered valerylene and a small quantity of a polymeric hydrocarbon. The *monohydrochloride*, $C^5H^8.HCl$, is a very mobile liquid insoluble in water, lighter than that liquid, and having an odour like that of amyl chloride, but stronger and more unpleasant; it boils at about 100°, that is to say, 10° higher than amylene hydrochloride. The *dihydrochloride*, $C^5H^8.H^2Cl^2$, is a liquid boiling at 150°–152°, heavier than water and insoluble therein.

Valerylene Monohydrobromide (v. 982) boils at 115°; the dihydrobromide at 180°, with slight loss of hydrobromic acid.

Fuming hydroiodic acid unites directly with valerylene on agitation, forming two compounds, of which only the *monohydriodide*, $C^5H^8.HI$, has been isolated. It is a mobile liquid, sinking in water, and boiling at 140°–142°.

Acetates.—When the dihydrobromide is heated to 100° for eight hours with silver acetate suspended in ether, a product is obtained, which, when freed from silver bromide, silver acetate, and ether, contains mono- and di-acetate of valerylene:

and

Valerylene monoacetate is obtained by saturating the portion of the liquid which distils between 120° and 145° with sodium carbonate and distilling that which remains undissolved. It floats on water; is insoluble therein; has a fragrant odour like that of essence of pears, but more pungent; boils at about 153° ; and is decomposed by pulverised potassium acetate, with formation of valerylene hydrate (corresponding to amylene monohydrate or secondary amyl alcohol). This latter is an aromatic liquid lighter than water, insoluble therein, boiling at 115° – 120° . Sodium dissolves in it, with evolution of hydrogen, forming a solid compound, which is decomposed by water, with reproduction of the monohydrate. *Valerylene diacetate*, $C^3H^4 \cdot H^2 \cdot (C^2H^3O^2)^2$, is a somewhat thickish liquid, insoluble in water, boiling at about 205° . It is decomposed by potash, yielding acetic acid and probably valerylene-dihydrate.

Polymerides of Valerylene are formed by the action of sulphuric acid on valerylene. When the hydrocarbon is gradually mixed with strong sulphuric acid in a cooled vessel, a dark violet-red layer separates, which, by washing with water and alkali, is converted into a rather viscid yellow oil. The acid separated therefrom and neutralised with barium carbonate, yields only a small quantity of a hygroscopic salt. The yellow oil yields by fractional distillation:—1. *Divalerylene hydrate*, $2C^3H^4 \cdot H^2O$, a mobile liquid lighter than water, insoluble therein, boiling at 175° – 177° , and having a strong odour like that of peppermint oil and of turpentine oil. This compound is perhaps the ether of the above-mentioned valerylene monohydrate.—2. *Trivalerylene*, C^6H^6 , a yellow oily liquid distilling between 265° and 275° , having a sp. gr. of 0.862 at 15° , smelling like turpentine oil, with which indeed (like valerylene itself) it is polymeric.

Still higher polymerides of valerylene are contained in the increasingly viscid portion of the product of the action of sulphuric acid on valerylene, which boils above 280° and towards 350° , and in the brown-yellow mass which separates on cooling. Sulphuric acid diluted with one-third of its volume of water, acts on valerylene in the same manner as the concentrated acid, but less energetically; if the acid is diluted with half its weight, or nearly an equal volume, of water, the entire quantity of valerylene may be treated with it at once, since the mixture does not become hot till after frequent agitation. In proportion as the acid is more dilute, the product becomes richer in the ether, $2C^3H^4 \cdot H^2O$, and in trivalerylene. Zinc chloride at 160° – 180° produces on valerylene the same transformations as sulphuric acid (Reboul, *Compt. rend.* lxi. 419; *Bull. Soc. Chim.* [2] viii. 190).

VANADIUM. Atomic Weight, 51.3 (Roscoe, *Phil. Trans.* 1869, p. 679; 1870, p. 317; *Proc. Roy. Soc.* xviii. 37, 316; *Chem. Soc. J.* [2] viii. 344; ix. 23).

Metallic Vanadium. The only method by which this metal can be obtained in the pure state is by the reduction of a vanadium chloride (free from oxygen) in hydrogen gas. Roscoe has obtained it by heating the pure dichloride to redness for 40 to 80 hours in a stream of perfectly pure and dry hydrogen. The process is extremely difficult, owing to the avidity with which the reduced metal absorbs oxygen at a red heat, rendering it necessary to exclude every trace of air and moisture during the reduction. The chloride to be reduced is placed in a platinum boat within a porcelain tube, as the metal acts violently on glass and porcelain, and tubes of platinum are porous at a red heat.*

Metallic vanadium thus prepared appears under the microscope as a shining crystalline mass, having a strong silver-white lustre. It does not oxidise or even tarnish in the air at ordinary temperatures, or even at 100° ; does not decompose water at 100° ; and may be moistened with water and dried in a vacuum without gaining weight. It does not melt or volatilise at a bright red heat in hydrogen. The powdered metal thrown into a flame burns with the most brilliant scintillations. Heated quickly in oxygen, it burns vividly, forming the pentoxide; but when slowly ignited in air, it first glows and forms a brown oxide (possibly V^2O), then again absorbs oxygen and is converted into black trioxide and blue tetroxide, till at last it attains its maximum degree of oxidation. It is not soluble in *hydrochloric acid*, either hot or cold; strong *sulphuric acid* dissolves it on heating, forming a yellow solution; *hydrofluoric acid* dissolves it slowly with evolution of hydrogen; *nitric acid* of all strengths acts violently on it, evolving red fumes and forming a blue solution. Fused with *sodium hydrate*, the metal dissolves, with evolution of hydrogen and formation of a sodium vanadate. In a current of *chlorine*, the metal takes fire, and

* For a description and figure of the apparatus used, see the paper above cited in the *Philosophical Transactions* or the *Journal of the Chemical Society*.

forms the reddish-black tetrachloride; heated in a current of pure *nitrogen* it is converted into mononitride.

By igniting one of the solid chlorides of vanadium with sodium in an atmosphere of hydrogen, and lixiviating the product, a light finely-divided black powder (trioxide) was obtained, which remained suspended and was soluble in hydrochloric acid, and a heavier grey powder insoluble in hydrochloric acid, consisting of metallic vanadium with more or less oxide. When this metallic powder, after drying in a vacuum, was reduced at a low red heat in hydrogen gas, it took fire spontaneously even when cold, on exposure to air or oxygen, forming water and the blue oxide V_2O_4 . A portion of metal exposed to the air for some weeks slowly absorbed oxygen, and was converted into V_2O_5 .

Bromides and Oxybromides. The only bromide known is the tribromide VBr_3 , which is formed by passing bromine-vapour over red-hot vanadium mononitride. A vivid action then occurs, and dark brown vapours are formed, which condense to a greyish-black, opaque, amorphous mass of the tribromide. This compound is very unstable, losing bromine even in sealed tubes; very deliquescent; and when heated in the air quickly gives off all its bromine, and is converted into the pentoxide. When thrown into water, it rapidly dissolves, forming a brown liquid (in this respect resembling the trichloride), which, on addition of a few drops of hydrochloric acid, assumes a fine green colour, showing the presence of a hypovanadic salt. No free bromine or hydrobromic acid is given off on dissolving the tribromide in water. No volatile higher bromide is formed in the reaction of bromine on the nitride above described, for the excess of liquid collected in the receiver yields on distillation nothing but free bromine.

Vanadium Oxytribromide or Vanadyl Tribromide, $VOBr_3$, is obtained by passing pure and dry bromine over red-hot vanadium trioxide. It is a dark red transparent liquid, evolving white fumes in contact with the air, decomposing suddenly at 180° , and slowly at ordinary temperatures. Under a pressure of 100 mm. it boils at 130° – 135° , and may be distilled almost without decomposition. Its sp. gr. at 0° is 2.967. It dissolves in water, forming a yellow solution.

Vanadium Oxydibromide or Vanadyl Dibromide, $VOBr_2$, formed by the sudden decomposition of the preceding compound at temperatures above 100° , or by its slow decomposition at ordinary temperatures, is a yellowish-brown, very deliquescent solid, which dissolves in water, forming a blue solution of a vanadous salt. Heated in the air, it gives off all its bromine, and is converted into the pentoxide.

Chlorides. Three of these compounds have been obtained, viz. $VC l_2$, $VC l_3$, and $VC l_4$.

The *dichloride*, $VC l_2$, prepared by passing the vapour of the tetrachloride, mixed with hydrogen, through a glass tube heated to dull redness, crystallises in bright apple-green micaceous plates, having a sp. gr. of 3.23 at 18° . When strongly heated in hydrogen, it gives up all its chlorine and is reduced to metal. It is extremely hygroscopic, and when thrown into water, forms a violet solution identical in tint with the liquid containing a hypovanadous salt obtained by reducing vanadic acid in solution with zinc or sodium amalgam (v. 987), and like that liquid bleaches strongly by reduction. Its solution is oxidised by permanganates, according to the equation:

The *trichloride*, $VC l_3$, is best prepared by the quick decomposition of the tetrachloride at its boiling point, or by its slow decomposition at ordinary temperatures. The crystalline body thus obtained may be freed from adhering tetrachloride by drying in carbon dioxide at 160° . It crystallises in splendid peach-blossom-coloured shining tables, closely resembling chromic chloride, and having a sp. gr. of 3.00 at 18° . It is non-volatile in hydrogen, and decomposes when heated in the air, glowing, with absorption of oxygen, and forming the pentoxide. Heated in hydrogen it is first reduced to dichloride, and then at a higher temperature to metallic vanadium. It is extremely hygroscopic, deliquescent to a brown liquid on exposure to the air. When thrown into water it does not at once dissolve, but as soon as the crystals get moistened, a brown solution is formed, which turns green on addition of a drop of hydrochloric acid, and then contains a hypovanadic salt. This green tint is identical with that produced by reducing a solution of vanadic acid with magnesium (v. 987). The solution of the trichloride is oxidised by permanganates according to the equation:

The *tetrachloride*, $VC l_4$, is formed as a dark reddish-brown volatile liquid, when metallic vanadium or the mononitride is heated in a current of chlorine; also when

the vapour of the oxytrichloride (v. 992), mixed with excess of chlorine, is passed several times over a column of red-hot charcoal; the whole of the oxygen may thus be removed and ultimately perfectly pure tetrachloride obtained. The tetrachloride prepared by the first method may be purified by distillation in a current of chlorine, and afterwards in a current of carbon dioxide. The pure tetrachloride is a dark brown liquid having a sp. gr. of 1.8584 at 0°, boiling at 154°, and not solidifying at -18°. Neither at this nor at any higher temperature is it altered in its properties by treatment with chlorine. It is resolved quickly on boiling, slowly at ordinary temperatures, into the trichloride and free chlorine. When thrown into water, it immediately decomposes, forming a blue solution, identical in colour with that which is obtained by the reducing action of sulphurous or sulphydric acid on a solution of vanadic acid, and containing a vanadous salt derived from the tetroxide, V^2O^4 . The solution treated with permanganate is oxidised according to the equation:

The aqueous solution of the tetrachloride does not bleach; but if the vapour be passed into water, a liquid is obtained which bleaches litmus. Vanadium tetrachloride acts violently on alcohol and ether, forming deep-coloured liquids.

When bromine and vanadium tetrachloride are heated together in a sealed tube, no combination takes place, but trichloride is deposited: hence it appears that vanadium does not readily form pentad compounds with the chlorous elements.

Iodine does not attack either trioxide or nitride of vanadium at a red heat.

Vanadium Mononitride, VN, has been already described (v. 987) as obtained by the action of ammonia on vanadyl trichloride. A more economical method is to subject ammonium metavanadate, NH^4VO^3 , at a white heat to a current of dry ammonia; the pure mononitride then remains behind. It may also be prepared by heating the trioxide or the dichloride to whiteness in a platinum tube through which dry ammonia gas is passed.

Metallic Vanadates. The analogy between the vanadates and phosphates has been already pointed out (v. 989). The vanadates examined by Berzelius and v. Hauer, were chiefly metavanadates, M^2VO^3 , or $M^2V^2O^6$, and anhydovanadates, $2MVO^3.V^2O^4$, or $M^2V^2O^6.V^2O^4$. Roscoe has lately obtained several orthovanadates, M^2VO^4 , and tetrabasic vanadates, or pyrovanadates, $M^4V^2O^7$.

The soluble vanadates of these three classes exhibit, at ordinary temperatures, an order of stability which is the reverse of that of the corresponding phosphates, the metavanadates being the most and the orthovanadates the least stable. Thus sodium orthovanadate, Na^2VO^4 , splits up in solution into caustic soda and the pyrovanadate; and the soluble pyrovanadates in aqueous solution are easily decomposed by carbonic acid into an alkaline carbonate and a monobasic or metavanadate. At high temperatures, on the other hand, the tribasic salts are the most stable; thus vanadium pentoxide, when fused with sodium carbonate, eliminates 3 mol. CO^2 , and forms an orthovanadate, but when boiled with a solution of sodium carbonate it forms a metavanadate. Hence, as most of the native vanadates are tribasic, we may assume that they have been formed at high temperatures.

The soluble orthovanadates form with *ferrie salts* a light brownish-yellow gelatinous precipitate; soluble in hydrochloric, insoluble in acetic acid; with *ferrous salts*, a dark grey precipitate; with *manganous salts*, brownish-yellow crystalline; with *zinc salts*, white gelatinous; with *cobalt salts*, brown-grey gelatinous; with *nickel salts*, canary-yellow crystalline; with *copper salts*, apple-green; with *mercuric salts*, orange-yellow; and with *aluminium salts*, a bright yellow gelatinous precipitate, soluble in excess of either reagent, the solution thus formed yielding a white precipitate on boiling.

Sodium Salts.—The *tri-sodic salt* or sodium orthovanadate, $Na^2VO^4 + 16H^2O$, remains as a white crystalline mass when a mixture of 3 mol. sodium carbonate and 1 mol. vanadium pentoxide is fused till no more carbon dioxide is evolved. This mass dissolves easily in water, and on addition of absolute alcohol two layers of liquid are formed, the lower of which solidifies after a while to a mass of needle-shaped crystals having the composition above given. In analysing this and the following salt, the vanadic acid was precipitated in the form of the perfectly insoluble orthovanadate of lead (p. 1127); this was dried at 100° and weighed, then dissolved in nitric acid and decomposed by sulphuric acid, and the solution of vanadium pentoxide in excess of this acid gave on evaporation a finely crystalline mass. The filtrate from the lead precipitate yielded sodium sulphate on evaporation.

Tetrasodic Vanadate or *Sodium Pyrovanadate*, $\text{Na}_4\text{V}_2\text{O}_7 + 18\text{H}_2\text{O}$.—The trisodic salt, when repeatedly crystallised, splits up into the tetrasodic salt and caustic soda :

The tetrasodic salt crystallises in beautiful six-sided tables, easily soluble in water, insoluble in alcohol, and is precipitated by the latter liquid from aqueous solution in white scales having a silky lustre. As long as it contains free alkali or trisodic salt, it forms, on precipitation with alcohol, oily drops which gradually solidify.

The tetrasodic salt is always formed in the first instance when vanadium pentoxide is fused with excess of sodium carbonate, and can be easily obtained in the pure state by recrystallisation.

The corresponding *calcium* and *barium vanadates*, $\text{Ca}_2\text{V}_2\text{O}_7$, and $\text{Ba}_2\text{V}_2\text{O}_7$, are white precipitates obtained by adding the chlorides to a solution of tetrasodic vanadate. The calcium salt contains $2\frac{1}{2}$ mol. water; the barium salt is anhydrous. When calcium chloride is added to a solution of the trisodic salt, dicalcic vanadate is precipitated, and the solution contains calcic hydrate.

Lead Salts.—The *tripbumbic vanadate*, or *Orthovanadate*, $\text{Pb}(\text{VO}_4)_2$, is obtained as a light yellow insoluble powder on precipitating trisodic vanadate with a soluble lead salt. The *orthovanadato-chloride*, $3\text{Pb}_2(\text{VO}_4)_2 \cdot \text{PbCl}_2$, which occurs native as *vanadinite*, may be artificially prepared by melting for five hours a mixture of vanadium pentoxide, lead oxide, and lead chloride in the required proportions, with an excess of sodium chloride. After cooling, a greyish crystalline mass is left, containing cavities filled with long crystals having the same colour as the mass, and distinguishable under the microscope as six-sided prisms. The crystalline powder, after being freed by boiling from soluble chloride, exhibits the composition of native vanadinite; its sp. gr. at 12° is 6.707, that of the natural mineral 6.886. *Basic diplumbic Vanadate*, $2\text{Pb}_2\text{V}_2\text{O}_7 \cdot \text{PbO}$, is precipitated as a pale yellow powder when lead acetate is added to a solution of tetrasodic vanadate, the liquid acquiring an acid reaction. It is quite insoluble in water and in dilute acetic acid, but dissolves readily in nitric acid.

Silver Vanadates.—The *orthovanadate*, Ag_2VO_4 , is obtained as an orange-coloured precipitate on adding silver nitrate to a recently prepared and perfectly neutral solution of trisodic vanadate. It is insoluble in water, but dissolves readily in ammonia and in nitric acid. The *pyrovanadate*, $\text{Ag}_4\text{P}_2\text{O}_7$, separates on adding a neutral solution of silver nitrate to the corresponding sodium-salt, as a yellow, dense, crystalline precipitate, resembling in colour the ordinary phosphate of silver.

VAPOUR-DENSITY. A new method of determining vapour-densities, founded on the well-known method of Gay-Lussac, is described by A. W. Hofmann (*Deut. chem. Ges. Ber.* 1868, i. 198). A graduated glass tube about a metre long and 15 to 20 mm. wide, is filled with mercury and inverted in a mercury trough, whereby a barometric vacuum, 20 to 30 mm. high, is formed at the top. This part of the tube is enclosed in another tube 30 to 40 mm. wide and 80 to 90 mm. long, drawn out at the top to a conducting tube of moderate width, which is bent at right angles, and connected with a glass or copper vessel in which water, aniline, or other liquid can be boiled. The outer tube is closed at bottom with a cork having two apertures, one to admit the barometer-tube, the other for an escape-tube. By this arrangement, a stream of vapour of water, aniline, or other volatile liquid can be made to pass through the space between the two tubes, so as to keep the upper part of the barometer-tube at the temperature required for the determination. The substance whose vapour-density is to be determined, is introduced into the barometric vacuum in small glass tubes fitted with ground stoppers, which are forced out by the tension of the vapour. The great advantage of this method is that, under the very small pressure to which the enclosed vapour is subjected—which may be reduced to 20 or even 10 millimetres of mercury—the determinations may be made at comparatively low temperatures. Thus, in the case of liquids boiling under the ordinary pressure at 120° or even 150° , the vapour-density may be accurately determined at the temperature of boiling water. For the working details and a figure of the apparatus, we must refer to the original paper.

VIRIDIC ACID. This acid, obtained by Rochleder from cassianic acid, may also be prepared directly from coffee-berries, by boiling them with ether-alcohol to remove the fat, and exposing them in the form of moist powder to the air. The powder turns green in a few days, and if then exhausted with acetic acid and alcohol, yields viridic acid as a brown amorphous mass (C. O. Cech, *Ann. Ch. Pharm.* cxliii. 366).

VOLTAITE. This mineral has been found, in non-cleavable octohedrons with cubic and dodecahedral faces, mixed with ferrous sulphate, in an iron mine at Kremnitz. Colour, black to violet; hardness, 3; sp. gr. 2.79. Analysis gave 48.0 p. c. SO_3 , 5.1 Al_2O_3 , 12.9 Fe_2O_3 , 15.6 FeO , 3.6 K_2O , and 15.3 H_2O (Tschermak, *Wun. Akad. Ber.* lvi. [1] 824).

W

WALNUT. See JUGLANS (p. 763).

WATER. On the electrolysis of water in contact with silver, see Rundspaden, (*Ann. Ch. Pharm.* cli. 306; *Zeitschr. f. Chem.* [2] vi. 49).

On the influence of water on double decompositions, and on the accompanying thermic effects, see Marignac (*Compt. rend.* lxi. 1180; *Zeitschr. f. Chem.* [2] vi. 69).

WAX from **STRAW.** The straw of cereals yields a white wax, greasy to the touch, insoluble in water and in caustic alkalis, soluble in alcohol, especially when warm, also in ether and in carbon bisulphide, and crystallising from alcoholic solution by slow cooling in small tables or shining nacreous scales. At 42° it melts to a colourless oil, which makes grease spots on paper, and solidifies on cooling to a hard brittle mass. It boils at about 300° , almost without residue; the portion distilling over between 300° and 303° melts as before at 42° . The wax is easily attacked by bromine at a gentle heat. Nitric acid, even when hot and concentrated, attacks it with difficulty, forming a compound soluble in caustic alkalis. Strong sulphuric acid attacks the wax when heated, forming a solution from which water throws down a flocculent precipitate probably consisting of the original compound (Radziszewski, *Deut. chem. Ges. Ber.* ii. 207).

WOOL. On the composition of raw sheep's wool, see Märcker & Schulze (*J. pr. Chem.* cviii. 193; *Zeitschr. f. Chem.* [2] vii. 281).

X

XANTHINE. $\text{C}_5\text{H}_4\text{N}_4\text{O}_2$. Neubauer's method of estimating xanthine and separating it from sarcine in muscular flesh, is given under SARCINE (p. 1013); see further *Zeitschr. f. Chem.* [2] v. 31.

XENOL. Syst. with XYLENOL.

XONALITE. A hydrated calcium silicate, found at Tetela de Xonatlá in Mexico. It occurs intergrown with apophyllite and bustamite, forming white or bluish-grey concentric layers. Fine-grained or compact; very hard and tough; sp. gr. 2.710 to 2.718. Analysis gave for the white variety, A, and the grey variety, B, the following numbers:

SiO_2	CaO	MgO	MnO	FeO	H_2O
40.58	43.56	—	1.79	1.31	3.70 = 99.94
50.25	43.92	0.19	2.28		4.07 = 100.71

agreeing nearly with the formula $4\text{CaSiO}_3 + \text{H}_2\text{O}$ (Rammelsberg, *Jahrb. Min.* 1866, p. 718).

XYLENEDIAMINE. Syn. with XYLYNEDIAMINE (p. 1132).

XYLENOL. $\text{C}_8\text{H}_{10}\text{O}$ = $\text{C}_6\text{H}_4(\text{CH}_3)_2\text{OH}$.—*Dimethyl-phenol*, *Xenol*, *Xylylic phenol* (Wroblevsky, *Zeitschr. f. Chem.* [2] iv. 232; *Bull. Soc. Chim.* [2] x. 286; Wurtz, *Jahresb.* 1868, p. 459).—Prepared by fusing the potassium salt of xylyl-

sulphurous acid, $C^6H^5SO^3K$, with twice its weight of potassium hydrate, decomposing the resulting mass with hydrochloric acid, and distilling in a current of steam, or digesting with ether, which dissolves out the xyleneol. According to Wroblevsky, it is a liquid boiling at 214.2° (corr.), having a sp. gr. of 1.0233 at 22° , and smelling like phenol; slightly soluble in water; coloured faintly greenish by ferric chloride. By treatment with sodium and carbon dioxide, it is converted into xyletic acid, $C^6H^5O^3$ (Wroblevsky).

Wurtz, by decomposing the fused alkaline mass obtained, as above, with hydrochloric acid, digesting it with ether, and distilling, obtained a liquid which passed over at 210° , and when exposed to a winter temperature, separated into two isomeric modifications, one crystalline, the other liquid.—*a.* *Solid xyleneol* dissolves abundantly in alcohol and ether; melts at 75° to a liquid which has a sp. gr. of 0.9709 at 81° , and contracts considerably in solidifying; it boils at 213.5° , and when heated above its melting point gives off copious fumes which condense on the cooler parts of the vessel.—*b.* *Liquid xyleneol* is colourless and strongly refractive; has a sp. gr. of 1.036 at 0° , and 0.9700 at 81° (expansion-coefficient 0.000868); boils at 211.5° (bar. at 759.7 mm.); mixes in all proportions with alcohol and ether; is slightly soluble in water, and itself dissolves small quantities of that liquid.

Solid xyleneol is also produced by heating the neutral potassium salt of oxymesitylenic acid with excess of potash, just as phenol is obtained from potassium salicylate:

The xyleneol thus prepared agrees almost exactly in its physical properties with that obtained by Wurtz (melts at 73° and boils at 216°). Now as mesitylenic acid, when heated with lime, yields metaxylene (p. 293), in which the two methyl-atoms occupy the places 1, 3, it follows that in the phenol obtained from oxymesitylenic acid, the two methyl-atoms will also occupy a similar position, having the hydrogen-atom between them. The isomerism of solid (*a*) and liquid (*b*) xyleneol may accordingly be represented as follows:

Bromine converts xyleneol into tribromoxyleneol, $(C^6H^3Br^3O)$, which forms golden-yellow shining crystals, melting at 141° (Wroblevsky).

When *a*-xyleneol suspended in water and cooled is treated with bromine, and the excess of bromine evaporated, dibromoxyleneol, $(C^6H^4Br^2O)$, remains as a laminar mass, which crystallises from alcohol in large golden-yellow plates, melting at 176° , and subliming at higher temperatures in delicate golden-yellow spangles. It is easily soluble in hot, less easily in cold alcohol, insoluble in water and in sodium carbonate; dissolves in alkalis, especially when warmed, but apparently not without decomposition (Fittig a. Hoogewerf, *Zeitschr. f. Chem.* [2] v. 170).

Xyleneol is isomeric with Müller's xylylic phenol, with phlorol, and with the so-called tolylic alcohol, $C^6H^4 \begin{Bmatrix} CH^3 \\ CH^2OH \end{Bmatrix}$, better called xylylic alcohol (v. 1062).

XYLETIC ACID, $C^6H^5O^3 = C^6H^5O.CO^2H$, isomeric with phloretic, tropic, and melilotic acids, is produced by treating xyleneol with sodium and carbon dioxide. When separated from the resulting sodium salt by hydrochloric acid, and freed from admixed xyleneol by a current of steam, it forms white crystals, melting at 155° , and sublimable. It is more soluble in hot than in cold water; colours ferric chloride violet. The barium salt, $(C^6H^5O^3)^2Ba + H^2O$, and the calcium salt, $(C^6H^5O^3)^2Ca + 2H^2O$, form needle-shaped crystals, which give off their water at 150° (Wroblevsky, *loc. cit.*).

XYLIC or XYLYLIC ACID. $C^6H^{10}O^2 = C^6H^4(CH^3)^2.CO^2H$. Two modifications of this acid, distinguished as *xylic* and *paraxylic*, are formed, together with xylic acid, $C^6H^4(CH^3).(CO^2H)^2$, by oxidising pseudocumene (prepared by methylation of metaxylene, p. 296) with dilute nitric acid (1 vol. acid of sp. gr. 1.4 and 2 vol. water) at the boiling heat. At the end of the reaction, a crystalline mass separates; and on repeatedly boiling this mass with water, xylic and paraxylic acids pass over, while xylic acid and nitro-acids remain behind. The distillates are supersaturated with sodium carbonate and boiled down (whereupon admixed nitropseudocumene passes over) and the concentrated solution is supersaturated with

hydrochloric acid. The mixture of acids thereby separated is finally treated with tin and hydrochloric acid, to remove the nitro-compounds, and converted into calcium salts, which may be separated by their different solubility in water, the xylate being more soluble than the paraxylate.

Xylic acid crystallises from alcohol in colourless monoclinic prisms, melting at 120° . It also melts in boiling water, then dissolves, and crystallises for the most part in needles on cooling. In alcohol it is much more soluble, especially at the boiling heat.

Calcium xylate, $(C^6H^4O^2)^2Ca + 2H^2O$, crystallises in hard, transparent, colourless, monoclinic prisms, which dissolve abundantly, though slowly, in water. The *barium salt*, $(C^6H^4O^2)^2Ba + 8H^2O(?)$, is very soluble in water, and remains on evaporation as a radio-crystalline mass.

By potassium chromate and dilute sulphuric acid, it is easily and completely oxidised to carbonic and acetic acids, a small quantity of xylidic acid being sometimes also formed as a secondary product.

Paraxylic acid crystallises from alcohol in rather large concentrically grouped, colourless, pointed prisms, melting at 163° . It is nearly insoluble in cold, very sparingly in boiling water, does not melt when boiled with water, dissolves very easily in alcohol. When oxidised with nitric acid, it yields xylidic acid identical with that which is obtained by oxidation of xylic acid. *Calcium paraxylate*, $(C^6H^4O^2)^2Ca + 3\frac{1}{2}H^2O$, crystallises in soft white spicules, often grouped in tufts, dissolving quickly when warmed with water. The *barium salt*, $(C^6H^4O^2)^2Ba + 4H^2O$, crystallises in tufts or stellate groups of hard colourless needles. It is more soluble in water than the calcium salt, but less soluble than barium xylate (Fittig a. Laubinger, *Zeitschr. f. Chem.* [2] iv. 597).

In pseudocumene, $C^6H^2(CH^3)^3$ (p. 296), as shown by Bieber a. Fittig (*ibid.* v. 434), the three methyl-atoms occupy the relative positions denoted by 1, 3, 4. Now, as this hydrocarbon, when oxidised with nitric acid, yields simultaneously the two isomeric acids xylic and paraxylic, it follows that two of its methyl-atoms are oxidised with equal facility to CO^2H . The positions of these two equally oxidable methyl-atoms may be determined by removing the carboxyl-groups from the two acids, and observing what modifications of xylene or dimethyl-benzene $C^6H^4(CH^3)^2$, are thereby produced. Now it is found that xylic acid, when heated with lime, yields metaxylene or isoxylene (1, 3), and paraxylic acid similarly treated yields orthoxylene (3, 4); hence it appears that in the formation of xylic acid from pseudocumene, the methyl-atom occupying the position 4, is oxidised to carboxyl, and in the formation of paraxylic acid, the methyl-atom occupying the position 1, undergoes that change: thus;

		1	2	3	4	5	6
Benzene	C^6	H	H	H	H	H	H
Pseudocumene . .	C^6	(CH^3)	H	(CH^3)	(CH^3)	H	H
Xylic acid	C^6	(CH^3)	H	(CH^3)	(CO^2H)	H	H
Paraxylic acid . .	C^6	(CO^2H)	H	(CH^3)	(CH^3)	H	H

Identical with the xylic acid above described is that which Schaper obtained by oxidising cumene (prepared by dry distillation of calcium cumene-sulphate) with dilute nitric acid: melting point 125° (*Zeitschr. f. Chem.* [2] v. 545); and probably also the acid melting at 122° , which Kekulé obtained by the action of carbon dioxide and sodium on bromoxylene. The xylic acid described by Hirzel a. Beilstein, as melting at 204° , and as yielding insolulinic acid by further oxidation, and the liquid xylic acid described by Kügler a. Beilstein, both produced by oxidation of cumene (v. 1062) seem to require further investigation.

XYLIDIC ACID. $C^6H^4O^4 = C^6H^2 \begin{Bmatrix} CH^3 \\ CO^2H. \\ CO^2H \end{Bmatrix}$.—This bibasic acid, isomeric with

uvitic or mesidic acid, is formed, as above stated, by the oxidation of xylic or paraxylic acid, or directly from pseudo-cumene, by simultaneous oxidation of the methyl-atoms 1 and 4, in the same molecule of the hydrocarbon. It is a white, amorphous, bulky mass, nearly insoluble in cold water, very slightly soluble in boiling water, easily in alcohol, especially when warm, and crystallises therefrom, by spontaneous evaporation, in white granulo-crystalline nodules. It melts at 280° – 283° , and sublimes easily (especially in a stream of dry carbon dioxide), in hard colourless needles melting at 291° . *Calcium xylidate*, $C^6H^4O^4Ca$, forms indistinct white scales, very soluble in water, and containing water of crystallisation, which they give off over oil of vitriol. The *barium salt*, $C^6H^4O^4Ba$, remains on evaporation as a radio-crystalline mass, more soluble in water than the calcium salt, precipitated from the concentrated solution by alcohol, in colourless flocks. The *silver salt* is obtained as a white flocculent pre-

precipitate, moderately soluble in hot water. The solution of the ammonium salt forms with cupric salts a light blue flocculent precipitate, soluble in a large quantity of water; no precipitate with zinc salts (Fittig a. Laubinger, *loc. cit.*).

XYLIDINE. $C^8H^{11}N = C^8H^9(NH^2)$. *Amido-xyline*.—The α and β modifications of nitro-ethylbenzene (p. 292), yield by reduction corresponding xylidines. The α -xylidine thus obtained is a clear liquid, having a sp. gr. of 0.975 at 22°, and boiling at 213°–214°. The β -xylidine has a sp. gr. of 0.975 at 22°, and boils at 210°–211°. Both turn brown in contact with the air. The corresponding acetoxylicides, $C^8H^9.NH(C^2H^3O)$, were prepared by prolonged boiling of the bases with glacial acetic acid and recrystallisation from alcohol. α Acetoxylicide melts at 94°, and boils at 315°–317°, dissolves sparingly in boiling water, and separates on cooling in small very slender needles. β Acetoxylicide boils at 304°–305°, and is easily soluble in boiling water (Beilstein a. Kuhlberg, *Zeitschr. f. Chem.* [2] v. 525).

Genz (*ibid.* vi. 216) has prepared acetoxylicide from xylidine boiling at 212°–213°, obtained by fractional distillation of aniline-oils of high boiling point. The acetoxylicide, slowly crystallised from boiling water, forms needles an inch long, melting at 112°–113°, easily soluble in alcohol and ether. By boiling with potash it is resolved into xylidine and acetic acid. On agitating its saturated aqueous solution with bromine-water till the liquid becomes permanently yellow, and recrystallising the resulting reddish precipitate from hot water, *acetobromoxylide*, $C^8H^8Br.NH(C^2H^3O)$, is obtained, in colourless needles; by decomposition with potash it yields bromoxylidine.

Nitroxylidines or Nitroamidoxylenes. $C^8H^{10}N^2O^2 = C^8H^8(NO^2)(NH^2)$.—(Fittig, Ahrens a. Mattheides, *Ann. Ch. Pharm.* cxlvii. 15; *Jahresb.* 1867, p. 697).

Metanitroxylidine or *Nitro-amidonitroxylene*, obtained by the action of hydrogen sulphide on a solution of dinitro-metaxylene (p. 294) in alcoholic ammonia, crystallises from water or alcohol on cooling, in orange-red needles; from the latter, by spontaneous evaporation, in well-defined crystals apparently monoclinic. It is nearly insoluble in cold, sparingly soluble in hot water, easily in boiling alcohol, and melts at 123° (Fittig, Ahrens a. Mattheides). According to Luhrmann (*Ann. Ch. Pharm.* cxliv. 274) it melts at 130°, and sublimes without decomposition.

α *Nitro-paraxylidine* or α *Nitroamido-paraxylene*, prepared in like manner from a dinitroparaxylene (p. 291), crystallises from alcohol in long golden-yellow needles, which melt at 96°, sublime when carefully heated, are sparingly soluble in water, easily soluble in alcohol. From β dinitroparaxylene it was not found possible to obtain a well-characterised crystalline base. Trinitrometaxylene, treated with ammonia and hydrogen sulphide, is easily converted into the corresponding *dinitroamido*- and *nitrodiamidoxylenes*, which are identical with the bases obtained by Bussenius a. Eisenstück, from the so-called trinitropetrol (iv. 382). Trinitro-paraxylene is reduced in like manner to basic compounds, but they are resinous and difficult to separate (Fittig, Ahrens a. Mattheides).

Dixylylcarbtriimine, Dixylylguanidine, or Mexylidine, $C^{11}H^{11}N^3 =$

$N^3 \begin{Bmatrix} C^1 \\ (C^2H^2)^2 \\ H^1 \end{Bmatrix}$, produced by the action of dry gaseous cyanogen chloride on dry xylidine, forms large colourless plates, sparingly soluble in cold, more easily in hot water, easily in alcohol and ether. With platinic chloride it forms the crystalline double salt, $2(C^{11}H^{11}N^3.HCl).PtCl_4$ (Genz).

Xylidine-red. Xylidine boiling at 212°, prepared from aniline-oils of high boiling point, does not yield any red colouring matter when treated with the oxidising agents used for the production of rosaniline, either alone or when mixed with toluidine. But a mixture of the same xylidine with pure aniline (which yields no red colouring matter by itself) instantly acquires, on boiling with either of these oxidising agents, a splendid crimson colour, due to the formation of a colouring matter homologous with rosaniline. This product, which dyes wool and silk almost as brightly red as rosaniline itself, has probably the composition $C^{22}H^{22}N^4.H^2O = C^8H^9 + 2C^8H^{11}N + H^2O - 3H^2$ (Hofmann, *Zeitschr. f. Chem.* [2] v. 633).

Xylidine prepared by reduction of ethyl-benzene likewise boils at 212°, but does not yield any red product when boiled with oxidising agents, either alone, or mixed with toluidine, or even with aniline. It likewise differs from coal-tar xylidine in its colour, which resembles that of indigo prepared from aniline, and by the far greater solubility of its salts (Hofmann a. Martius, *ibid.* 693).

XYLINDEIN. A green colouring matter obtained by Rommier (*Compt. rend.*

lxvi. 108) from the greenish-blue decayed wood from which Fordos prepared his xylochloric acid (v. 1060). To prepare it, the dried and pulverised wood is exhausted with 1 p. c. potash or soda-ley; the filtered and expressed extracts are precipitated with hydrochloric acid; the bulky precipitate is washed with slightly acidulated water, then redissolved in dilute potash-ley, and reprecipitated with alcohol of 85 p. c., and a saturated solution of common salt free from lime and magnesia. Xylindrin is thereby precipitated, while humous substances remain in solution. This treatment is several times repeated, and the mass is finally washed with alcohol, dissolved in water, reprecipitated with hydrochloric acid, and dried under the air-pump. Xylindrin thus prepared contains 50.33 p. c. carbon, 5.33 hydrogen, 2.63 nitrogen, 41.81 oxygen, and traces of iron and calcium. It is amorphous, and of dark green colour. Water dissolves it easily (in the hydrated state), with splendid green-blue colour; sodium chloride and acids, excepting acetic acid, precipitate it from this solution with green colour. In alkalis and alkaline carbonates, it dissolves very easily with green colour, or greenish-yellow if the alkali is in excess, whereas xylochloric acid is insoluble in alkalis. Strong sulphuric, nitric, and hydrochloric acid dissolve it, with rapid decomposition. With lime and magnesia it forms lakes insoluble in water, alcohol, &c. It is insoluble in strong alcohol, ether, wood-spirit, carbon bisulphide and benzol; chloroform in contact with hydrated xylindrin acquires a faint blue colour. It is reduced like indigo by alcoholic potash and glucose, the solution turning brown. It dyes silk and wool blue-green, without the aid of mordants.

XYLINIC ACID. An acid existing, according, to Lefort (*Compt. rend.* lxi. 1235), together with unaltered cellulose, resins, humous substances and salts, in the wood of old oak, elm, and willow stems. It is prepared, like Rommieu's xylindrin, by extraction with weak alkaline-ley, precipitation with hydrochloric acid, and treatment of the washed precipitate with alcohol and ether. The acid thus obtained is described as a hard, black, tasteless and scentless mass, slightly soluble in water, insoluble in alcohol and ether, easily soluble in alkalis. With the alkalis it forms amorphous brown or reddish salts; its other salts are insoluble. Lefort assigns to the acid the formula $2C^{12}H^{14}O^4 + H^2O$; the barium and calcium salts exhibit corresponding composition.

XYLYL, XYLYLIC ALCOHOL, ACETATE, CHLORIDE, SULPHYDRATE, &c. See the compounds called TOLUYL, TOLUYLIC ALCOHOL, &c., v. 869, 870.

XYLYLAMINES (Pieper, *Ann. Ch. Pharm.* cli. 129).—Bases homologous with the benzylamines, produced by the action of ammonia on xylyl chloride, $C^8H^7Cl = C^8H^4 \begin{Bmatrix} CH^3 \\ CH^2Cl \end{Bmatrix}$. This chloride, prepared by passing chlorine into xylene at the boiling point, is heated in sealed tubes to 116° with strong alcoholic ammonia; the contents of the tubes are thrown on a filter; and the crystalline mass, containing a large quantity of sal-ammoniac, is washed several times with alcohol. The filtrate freed by distillation from the ammonia and the greater part of the alcohol, is then mixed with water, which throws down impure oily trixylylamine (C^8H^9N); and the crystalline mass remaining on the filter is drenched with water, which dissolves the hydrochlorides of xylamine and dixylamine, leaving trixylylamine undissolved. The solution of the mixed hydrochlorides when concentrated, first deposits the dixylamine salt, which may be purified by recrystallisation; the mother-liquor, evaporated to a small bulk and mixed with strong potash-ley, yields an oil consisting of xylamine salt mixed with dixylamine; and on drying this oil over sticks of potash and distilling at 210° xylamine passes over, while the dixylamine remains behind.

Xylamine, $C^8H^{11}N = N \begin{Bmatrix} C^8H^9 \\ H^2 \end{Bmatrix}$ isomeric with xylidine, is a colourless, oily strongly alkaline liquid, smelling like herring-pickle, floating on water, and boiling at 196° . It is soluble in alcohol and ether, insoluble in water. When exposed to the air, it rapidly absorbs carbonic acid and becomes solid. Its solution in dilute alcohol precipitates the hydrates from many metallic salts. The *hydrochloride*, $C^8H^{11}N.HCl$ crystallises in white needles, easily soluble in water and alcohol, and melting at 185° . The *platinohydrochloride*, $2(C^8H^{11}N.HCl).PtCl_4$, forms golden-yellow shining laminae. With *mercuric chloride* also xylamine hydrochloride forms a double salt which separates in white crystals.

The isomerism between xylamine and xylidine or amidoxylene is represented by the following formulæ:

Dixylylamine, $\text{C}^6\text{H}_4\text{N} = \text{N} \left\{ \begin{array}{l} (\text{C}^6\text{H}_5)^2 \\ \text{H} \end{array} \right.$, is a faintly yellowish alkaline oil, smelling like herring-pickle, lighter than water and insoluble therein, easily soluble in alcohol and ether; decomposes at 210° . Its *hydrochloride*, $\text{C}^6\text{H}_4\text{N} \cdot \text{HCl}$, forms white light needles melting at 198° , sparingly soluble in cold water, easily in hot water and in alcohol. The *hydrobromide*, $\text{C}^6\text{H}_4\text{N} \cdot \text{HBr}$, forms soft white needles which turn red when heated and melt at 195° – 196° . This salt is formed, together with toluic aldehyde, by the action of bromine and water on trixylylamine:

On heating the liquid, the toluic aldehyde passes over, while the dixylylamine hydrobromide remains behind.

Trixylylamine, $\text{C}^6\text{H}_4\text{N} = \text{N}(\text{C}^6\text{H}_5)^3$, is obtained pure by mixing the crude oily base separated as above described with hydrochloric acid, washing the resulting crystalline hydrochloride with water and ether, recrystallising it from alcohol, and heating the salt thus purified with potash-ley. Trixylylamine then separates as a viscid, colourless, slightly alkaline oil, having a peculiar odour, floating on water, insoluble therein, easily soluble in alcohol and ether; decomposed by distillation. The *hydrochloride*, $\text{C}^6\text{H}_4\text{N} \cdot \text{HCl}$, forms loose, delicate, snow-white needles, insoluble in water and ether, slightly soluble in cold, easily in hot alcohol, melting at 212° . Its alcoholic solution mixed with platonic chloride deposits the *platinochloride* by spontaneous evaporation, in hard yellow crystalline crusts.

XYLYLENE-DIAMINE, $\text{C}^6\text{H}_4\text{N}^2 = \text{C}^6\text{H}_4(\text{NH}^2)^2$.—*Diamidoxylyene* (Fittig, Ahrens a. Mattheides, *Ann. Ch. Pharm.* cxlvii. 15; *Jahresb.* 1867, p. 697). Produced by boiling dinitroxylyene (from coal-tar xylene) with tin and hydrochloric acid. Crystallises from water in colourless needles, which quickly become coloured on exposure to light. Dissolves easily in hot water and in alcohol, and melts at 152° . The *hydrochloride*, $\text{C}^6\text{H}_4\text{N}^2 \cdot 2\text{HCl}$, is very soluble in water, and separates from a solution mixed with strong hydrochloric acid, in monoclinic prisms, which become coloured on exposure to light. With *stannous chloride* it forms a double salt, $\text{C}^6\text{H}_4\text{N}^2 \cdot 2\text{HCl} \cdot \text{SnCl}^2$, also crystallising in monoclinic prisms. The *sulphate*, $\text{C}^6\text{H}_4\text{N}^2 \cdot \text{SO}^2\text{H}^2$, is a crystalline powder, sparingly soluble in alcohol.

Z

ZINC. Arsenical zinc may be purified by fusing the granulated metal in a crucible with alternate layers of sulphur and sodium carbonate, repeating the operation several times if the proportion of arsenic is large. The purified metal separated from the slag is then to be remelted with litharge, to remove traces of sulphur or sodium sulphide; it then takes up a small quantity of lead, which however does not interfere with its use for the evolution of hydrogen (Gunning, *Jahresb.* 1863, p. 238).

The action of *sulphuric acid* of different strengths upon pure zinc, has been examined by Calvert a. Johnson (*Chem. Soc. J.* [2] iv. 435). The quantities, dissolved by two hours' contact of 50 c. c. of the acid with 1 c. c. of the metal are given in the following table under s.

	$^{\circ}$	$\frac{s}{\text{grm.}}$		$^{\circ}$	$\frac{s}{\text{grm.}}$
$\text{SO}^3 \cdot \text{H}^2\text{O}$	ordinary	0	$\text{SO}^3 \cdot 6\text{H}^2\text{O}$	130°	0.456
"	130°	0.075	$\text{SO}^3 \cdot 6\text{H}^2\text{O}$	ordinary	0.027
"	150°	0.232	"	130°	0.337
$\text{SO}^3 \cdot 2\text{H}^2\text{O}$	ordinary	0.002	$\text{SO}^3 \cdot 7\text{H}^2\text{O}$	ordinary	0.018
"	130°	0.142	"	100°	3.161
"	150°	0.345	"	100°	3.800
$\text{SO}^3 \cdot 3\text{H}^2\text{O}$	ordinary	0.002	$\text{SO}^3 \cdot 8\text{H}^2\text{O}$	ordinary	0.035
"	130°	5.916	$\text{SO}^3 \cdot 9\text{H}^2\text{O}$	"	0.005
$\text{SO}^3 \cdot 6\text{H}^2\text{O}$	ordinary	0.049	$\text{SO}^3 \cdot 10\text{H}^2\text{O}$	"	0.033

Pure zinc with metallic surface is scarcely attacked by dilute sulphuric acid $\text{SO}^2 \cdot 9\text{H}^2\text{O}$; much more easily after its surface has become covered by exposure with a thin film of oxide. The action of the strong acid ($\text{SO}^2 \cdot \text{H}^2\text{O}$ and $\text{SO}^2 \cdot 2\text{H}^2\text{O}$) takes place at high temperatures, with evolution of sulphurous oxide; that of the weaker acid ($\text{SO}^2 \cdot 3\text{H}^2\text{O}$ to $\text{SO}^2 \cdot 6\text{H}^2\text{O}$) with continuous evolution of hydrogen sulphide and a small quantity of sulphurous oxide; and that of still weaker acid, with evolution of pure hydrogen.

In a solution of sodium chloride zinc dissolves with evolution of hydrogen, formation of zinc-sodium chloride, and separation of zinc oxide. The oxide dissolves in solution of sodium chloride, slowly in the cold, more quickly and abundantly when heated, the liquid acquiring an alkaline reaction (Siorsch, *Jahresb.* 1867, p. 257).

On the volumetric estimation of zinc by means of potassium ferrocyanide, see Renard (*Compt. rend.* lxvii. 450; *Jahresb.* 1868, p. 874; *Bull. Soc. Chim.* [2] xi. 473; *Zeitschr. f. Chem.* [2] v. 662).

For the separation of zinc from copper (in brass), Chancel mixes the solution of the two metals with sodium thiosulphate till it is completely decolorised. Sodium carbonate then precipitates the zinc, while the copper remains in solution. A small quantity of copper still remaining in the zinc carbonate may be removed by precipitation with hydrogen sulphide in acid solution (*Jahresb.* 1866, p. 803).

According to Schweikert (*Jahresb.* 1867, p. 847) zinc cannot be completely separated from phosphoric acid by fusion with sodium carbonate and lixiviation of the fused mass with water, inasmuch as part of the phosphoric acid remains combined with zinc oxide, and part of the latter passes into solution as sodium zincate. Moreover zinc oxide is not quite insoluble in sodium carbonate, and is not precipitated from the solution even by prolonged boiling. In precipitating zinc as carbonate, it is therefore necessary to avoid a large excess of sodium carbonate, or to neutralise it before heating.

An alloy of zinc and calcium containing 95.13 p. c. zinc, and 4.87 calcium, or Zn^{12}Ca , crystallises in obtuse quadratic octohedrons having a sp. gr. of 6.369 to 6.3726 (determined under rock-oil); it is decomposed by water (G. vom Rath, *Zeitschr. f. Chem.* [2] v. 665).

Commercial zinc-dust from the Rostberg works, was found by Aldendorf (*Jahresb.* 1866, p. 219) to consist of

Zn	Pb	Cd	ZnO	ZnCO^2	Insoluble matter
39.99	2.47	4.09	49.76	3.29	0.39

In consequence of the fine division of the zinc, this dust slowly decomposes water at ordinary temperatures, eliminating in 24 hours about its own volume of hydrogen. On leaving it in contact with dilute hydrochloric or sulphuric acid till hydrogen begins to escape, the greater part of the zinc oxide and carbonate are dissolved, while the metal remains as a fine grey powder, which when washed is well adapted for a reducing agent.

A compound of zinc chloride with ammonia, $\text{ZnCl}^2 \cdot 5\text{NH}^2 \cdot 4\text{H}^2\text{O}$, is formed when solid zinc chloride is gradually added to strong well-cooled aqueous ammonia, gaseous ammonia being passed into the liquid towards the end of the process. As soon as a considerable precipitate has formed, the vessel is to be closely gently warmed till the whole is dissolved, and left to settle. The ammonia-chloride then separates in regular octohedrons, with step-like cavities on their faces. The crystals when exposed to the air, immediately give off ammonia, become moist, and ultimately appear corroded and deliquesced. They dissolve easily in water, still more easily, with decomposition, in aqueous zinc chloride (E. Divers, *Chem. News*, xviii. 13); compare v. 1069.

Zinc Phosphides.—B. Renault (*Ann. Ch. Phys.* [4] ix. 166), by heating to whiteness a mixture of 1 mol. magnesium phosphate, ($\text{Mg}^2\text{H}^2\text{P}^2\text{O}^6$), 2 mol. zinc sulphide, and 7 at. carbon, in a coated retort connected with a red-hot earthen receiver, has obtained the following compounds of zinc and phosphorus: 1. A massive phosphide Zn^3P^2 of leaden colour and sp. gr. 1.21 at 14° . It is moderately permanent in the air, less fusible than zinc, and volatilises slightly above its melting point; heated with lead sulphide, it is converted into zinc sulphide, with separation of lead and phosphorus; it is also converted into sulphide by digestion with carbon bisulphide.—2. The same compound is obtained crystallised in interlaced needles having a faint metallic lustre, when the vapours are condensed in a larger and more strongly heated receiver. This crystallised phosphide is more easily alterable than the compact variety; gives off hydrogen phosphide in contact with the air; and is violently attacked by acids.—3. In certain preparations the needles were mixed with more

brilliant and permanent crystals having the composition Zn^2P^2 .—4. In capacious receivers there were also formed orange-coloured to cinnamon-red or metallically-lustrous interlaced needles, which, when heated in the air, burned with a phosphorus flame, leaving zinc phosphate. The red compound was likewise obtained, together with metallically lustrous needles, when phosphorus vapour, mixed with not perfectly dry hydrogen, was passed over red-hot zinc, or phosphorus vapour over red-hot zinc oxide: it appears to be an oxyphosphide varying in composition from $\text{Zn}^2\text{P}^2\text{O}$ to $\text{Zn}^2\text{P}^2\text{O}^4$; the metallically lustrous needles exhibited the composition $\text{Zn}^2\text{P}^2\text{O}^4$. The red compound is dissolved by hot hydrochloric and sulphuric acids, with formation of phosphorous acid.—5. A red phosphide, Zn^2P^4 , was obtained by treating a mixture of the crystalline oxyphosphides with hydrochloric acid.—6. On dissolving a large quantity of the compound Zn^2P^2 in dilute hydrochloric, sulphuric, or nitric acid, another phosphide, Zn^2P^2 , remained behind, as a yellow, amorphous, very inflammable powder, which detonated with the greatest violence, both when brought in contact with nitric acid and when mixed with potassium chlorate and lightly struck. The composition of all these zinc phosphides must be regarded as doubtful.

ZINC-ETHYL and ZINC-METHYL. $\text{Zn}(\text{C}^2\text{H}^3)^2$. For the preparation of zinc-ethyl, Wichelhaus heats zinc filings with iodide or bromide of ethyl in the water-bath in a retort with upright condenser, the pressure being increased by a column of mercury. The reaction is said to be finished in two or three hours, and to yield from 80 to 90 p. c. of the theoretical quantity (*Jahresh.* 1868, p. 428).

A mixture of zinc-ethyl with about twice its volume of carbon bisulphide, in a tube filled with carbon dioxide, begins to boil spontaneously, passing through all shades of red-brown till it becomes quite opaque, giving off at the same time a combustible gas consisting of hydrogen sulphide, vapour of carbon bisulphide, and ethylene. On the completion of the reaction, first at 50° – 60° , afterwards at 100° in a sealed tube, the contents of the tube, freed from excess of carbon bisulphide, consist of a brown shining mass, which, according to its weight and composition (somewhat variable indeed in different preparations), appears to consist of $\text{C}^2\text{H}^{10}\text{S}^2\text{Zn} = \text{CS}^2 + \text{Zn}(\text{C}^2\text{H}^3)^2$. This compound is insoluble in water, alcohol, and ether, but dissolves in acids with evolution of hydrogen sulphide. When subjected to dry distillation, or heated with hydrochloric acid, it gives off an oil having a pungent alliaceous odour, and boiling between 80° and 180° , the principal portion, which passes over between 130° and 150° , having the composition of amylene sulphide, $\text{C}^3\text{H}^{10}\text{S}$. When the purified oil is mixed in warm alcoholic solution with mercuric chloride, a white flocculent precipitate is formed, and the quickly filtered liquid deposits when heated iridescent laminae having the composition $\text{C}^2\text{H}^{10}\text{S} \cdot \text{HgCl}^2 \cdot \text{HgS}$. The amorphous substance separated by filtration appears to have the same composition as the crystals. With silver nitrate, in like manner, yellow microscopic needles are obtained, having the composition $\text{C}^2\text{H}^{10}\text{O} \cdot \text{Ag}^2\text{O} \cdot \text{AgNO}^2$. From the composition of the principal product, $\text{C}^2\text{H}^{10}\text{S} = \text{CS}(\text{C}^2\text{H}^3)^2$, it may be inferred that the action of zinc ethyl on carbon bisulphide takes place according to the equation:

Zinc-methyl unites with carbon bisulphide in a similar manner. Zinc-ethyl and mustard oil likewise form a brown amorphous solid compound difficult to isolate (*Grabowski, Ann. u. Ch. Pharm.* cxxxviii, 165).

According to Butlerow (*ibid.* cxliv, 39), the vapours of zinc-methyl, though they have a disagreeable odour and excite coughing, are not poisonous.

ZIRCON. Certain zirconia, of the variety called jargon, exhibit, both in their natural state and when fused with borax, very remarkable spectra, which were first described by Sorby (*Proc. Roy. Soc.* xvii. 511; *Chem. News*, xix. 122), and were supposed to indicate the presence of a new element, which was called *Jargonium*. Methods of obtaining jargonina, the oxide of this metal, and separating it from zirconia, and descriptions of its properties, were given by Sorby (*loc. cit.*) also by Church (*Chem. News*, xix. 121, and Loew, *ibid.* xx. 9). More recently, however, Sorby has shown that the peculiar spectra in question are due to the presence of certain compounds of uranic oxide with zirconia, these compounds giving spectra containing dark bands not exhibited either by uranic oxide or by zirconia alone. Artificially prepared compounds of uranic oxide with pure zirconia exhibit exactly the same spectra as those of the natural mineral. Hence Sorby concludes that the supposed jargonium has no existence (*Chem. News*, xxi. 73).

R. Hermann (*J. pr. Chem.* xcvii. 321; *Jahresh.* 1866, p. 191) has confirmed the results obtained by Berlin, respecting the earth called norria, found by Swanberg in

the zircons of Norway and other localities. Hermann's experiments show that zircon when contaminated with small quantities of alumina, exhibits properties exactly like those of the supposed corundum.

Zirconia has lately been brought into use in the oxyhydrogen blowpipe in place of platinum or magnesia. It possesses great radiating power and is very refractory, remaining quite unaltered after a month's use. To economise the costly material, only the outer portion of the cylinder is made of zirconia, the interior being composed of magnesia or fire-clay, the two substances being firmly pressed together. (See *Comptes Rendus*, lxi. 1040; *Ann. Ch. Phys.* [4] xiv. 11; *Dingl. pol. J.* clxxxix. 116; *Chem. News*, 1868, p. 536; *Chem. News*, xviii. 276).

ADDENDA.

INDIUM. According to a recent determination by Bunsen (*Pogg. Ann.* cxli. 1; *Chem. Soc. J.* [2] ix. 182), the specific heat of this metal is 0.067. This number multiplied by 75.63, the hitherto received atomic weight of indium (p. 729), gives for the atomic heat, the number 4.3, which does not agree with the law of Dulong and Petit. But if the atomic weight be taken as $1\frac{1}{2}$ times 75.6, or 113.4, the atomic heat becomes 6.5, which agrees nearly with the general law.

On this view, indium must be regarded as triatomic, and the formulæ of its principal compounds will be as follows:

Chloride	InCl ³
Indium and ammonium chloride	2NH ⁴ Cl.InCl ³ + H ² O
Yellow oxide	In ² O ³
Normal hydrate	InH ² O ³
Nitrate	In(NO ³) ³
Sulphate	In ² (SO ⁴) ³ + 9H ² O
Black oxide	InO ²
Green oxide	2InO.In ² O ³
Grey oxide	3InO.2In ² O ³

NORMAL AMYL-COMPOUNDS. The specific gravities and boiling points of some of these compounds, as determined by Lieben a. Rossi (*Gazzetta chimica italiana*, i. 314), are as follows:

	Boiling point	Specific gravity at		
		0°	20°	40°
Alcohol . .	137° (bar. at 0.740 met.)	0.8296	0.8168	0.8065
Chloride . .	106° " 0.7398 "	0.9013	0.8834	0.868
Bromide . .	128.7° " 0.7394 "	1.246	1.2234	1.2044
Iodide . .	155.4° " 0.7393 "	1.5435	1.5174	1.4961
Acetate . .	148.4° " 0.737 "	0.8963	0.8792	0.8645

The boiling points of the five known amyl alcohols go on increasing from the tertiary to the normal primary, as will be seen from the following comparison:

Primary			Secondary			Tertiary		
CH ³	H ³ C	CH ³	CH ³	H ³ C	CH ³	H ³ C	CH ³ CH ³	
CH ²			CH ²					
CH ²		CH		CH			COH	
CH ²		CH ²	CHOH	CHOH			CH ³	
CH ² OH		CH ² OH	CH ³	CH ³				
Normal amyl alcohol.	Iso-amyl alcohol.	Propyl-methyl carbinol	Isopropyl-methyl carbinol			Ethyl-dimethyl carbinol		
B. P. 137°	128°-132°	120°-123°	104°-108°			98.5°-100°		

NORMAL CAPROIC ACID, CH³CH²CH²CH²CH²COOH, is prepared by heating normal amyl bromide or iodide to 105° in a sealed tube with pulverised potassium cyanide dissolved in alcohol of 85° p. c., and heating the resulting normal amyl cyanide with alcoholic potash in an apparatus with reversed condenser. On distilling the resulting potassium salt with dilute sulphuric acid, and purifying the oily layer which separates by washing and distillation, normal caproic acid is obtained as a colourless liquid, which does not mix with water, has an odour fainter and somewhat less disagreeable than that of ordinary caproic acid, and a strongly acid taste. It boils at 201.5° (bar. at 0.7385 met.); the caproic acid prepared from ordinary amyl cyanide boils at 198° (Wurtz), at 199.7° (Lieben a. Rossi). The normal acid has a specific gravity of 0.9449 at 0°, 0.9294 at 20°, 0.9172 at 40°, and 0.8947 at 99.1° (Lieben a. Rossi, *loc. cit.*).
